**Abstract.** In the high latitude Arctic, wintertime sea ice and snow insulate the relatively warmer ocean from the colder atmosphere. While the climate warms, wintertime Arctic surface heat fluxes remain dominated by the insulating effects of snow and sea-ice covering the ocean until the sea ice thins enough or sea ice concentrations decrease enough to allow for direct ocean-atmosphere heat fluxes. The Community Earth System Model Large Ensemble (CESM1-LE) simulates increases in wintertime conductive heat fluxes in the ice-covered Arctic Ocean by  $\sim 7\text{-}11\text{ W m}^{-2}$  by mid-21<sup>st</sup> century, thereby driving an increased warming of the atmosphere. These increased fluxes are due to both thinning sea ice and decreasing snow on sea ice. The simulations analyzed here use a subgridscale ice thickness distribution. Surface heat flux estimates calculated using grid-cell mean values of sea ice thicknesses underestimate mean heat fluxes by  $\sim 16\text{-}35\%$  and overestimate changes in conductive heat fluxes by up to  $\sim 36\%$  in the wintertime Arctic basin even when sea ice concentrations remain above 95%. These results highlight how wintertime conductive heat fluxes will increase in a warming world even during times when sea ice concentrations remain high, and that snow and the distribution of snow play significantly impact large-scale calculations of wintertime surface heat budgets in the Arctic.

## 1 Introduction

The Arctic is warming rapidly, and much more rapidly than lower latitudes. This Arctic amplification (AA) is due to a combination of a number of related mechanisms, including sea ice loss, lapse rate and Plank feedbacks, and changing water vapor and clouds, among others (e.g. Graverson and Wang, 2009; Kumar et al, 2010; Screen et al., 2013; Pithan and Mauritsen, 2014; Vavrus, 2004; Feldl et al., 2020). Sea ice loss contributes to increased surface warming through two primary methods: an albedo feedback, and an insulating effect. The albedo feedback results from sea ice concentration losses that expose dark ocean water and sea ice surface state changes, including reduced snow cover and increased ponding, that darken the ice surface. These decrease the surface albedo and increase surface absorption of incoming radiation. The insulating effect results from thinning of the sea ice and overlying snow: in the winter, sea ice and snow insulate the relatively warmer ocean from the colder atmosphere. As sea ice and snow thin, more heat can be conducted through the sea ice to the atmosphere, influencing the ice-atmosphere exchange. Thinning ice and snow and increasing conductive heat fluxes can also lead to increased basal sea ice growth – a feedback in a warming world that is seen temporarily in climate projections before warming temperatures overwhelm this feedback and ice growth declines (e.g. Petty et al., 2018; Keen et al, 2020).

A large body of previous research has investigated the interactions between sea ice loss and AA. Most of the published research and the majority of the ongoing Polar Amplification Model Intercomparison Project (PAMIP) experiments focus on the influence of changes in sea ice concentration (SIC) on Arctic warming (e.g. Peings & Magnusdottir, 2014; Sun et al., 2015; 35 Smith et al., 2019; Sun et al., 2015). Less attention has been paid to the influence of winter sea ice thinning on Arctic surface warming, in part because observations of sea ice thickness (SIT) have only recently become more readily available, and in part because the effects of SIC losses tend to be large compared to those from SIT changes. Although wintertime SIC in the central Arctic remain high and have changed very little over the satellite era, the sea ice has thinned dramatically (e.g. Kwok and Rothrock, 2009; Kwok, 2018). Sea ice volume has decreased by roughly 66% since submarines have been measuring (1958- 40 1976) – and by 50% since 1999 (Kwok, 2018; Lindsay and Schweiger, 2015).

Recent work with atmosphere-only models over both the historical time period and future scenarios suggest that the atmospheric response to SIT changes are strongest in the cold season and at the surface, with atmospheric responses to SIT changes of similar or smaller magnitudes than the responses to SIC changes (e.g. Gerdes, 2006; Krinner, 2010; Lang et al., 45 2017; Labe et al., 2018b; Sun et al., 2017). There is qualitative agreement that the inclusion of SIT changes along with SIC changes lead to an enhancement of surface AA, although the range across different studies is large: two studies focused on late 20<sup>th</sup>-early 21<sup>st</sup> century found annual AA enhanced by ~37-50% with the inclusion of SIT changes (Lang et al., 2018; Sun et al., 2017), whereas AA increased by ~10% in the future simulations (2051-2080) of Labe et al. (2018b).

50 Our understanding of the influence of SIT on winter surface AA is further complicated by the presence of snow on sea ice, as well as the heterogeneous distribution of both snow and sea ice thicknesses. Snow is a more effective insulator than sea ice – and relatively small changes in snow thicknesses can result in large changes in conductive heat fluxes through the ice with consequent impacts on ice-atmosphere exchange. To our knowledge, there have been relatively few basin-scale studies on the effects of snow-on-sea-ice on the winter surface heat budgets in the Arctic in a changing climate. Previous work investigating 55 SIT changes on winter Arctic warming have not typically considered the effects of changing snow cover and often exclude this in the experimental design. For example, Lang et al., (2018) used atmosphere only models that do not allow snow to accumulate on sea ice. Furthermore, previous work with atmosphere-only models specifies grid-cell averaged values for SIT, thus calculating conductive fluxes (which are inversely related to sea ice and snow thicknesses) from an average SIT rather than as a sum over a sub-gridscale thickness distribution. This introduces errors relative to fully-coupled model simulations 60 which typically include a treatment of subgridscale ice thickness variations. These sources of errors and uncertainties also apply to global reanalysis products, most of which use constant sea ice thicknesses and no snow on sea ice for their product estimates (e.g. Wang et al., 2019) and show particularly large errors over the Arctic Ocean (e.g. Bromwich et al., 2018; Jakobson et al., 2012 and references therein). In particular, the lack of snow on sea ice in reanalysis products and the influence on the conductive heat flux results in a warm bias relative to observations (Batrak and Müller, 2019)

In this study we investigate the influence of SIT, snow thickness and heterogeneity in these fields on the Arctic winter energy budget in the climate modeling environment. We explore how projected thickness changes in both sea ice and snow influence conductive heat fluxes and ice-atmosphere heat exchange. We further investigate the importance of heterogeneity in sea ice and snow thicknesses at a model sub-gridcell level, how this impacts conductive heat flux calculations, and quantify the errors that are introduced by using grid-cell average SITs rather than heterogeneous fields. We explore how the wintertime Arctic heat fluxes change during a time period (1950-2070) when winter Arctic basin SICs remain high while ice and snow show dramatic thinning. This allows us to elucidate the dynamic nature of the influence of sea ice and snow thicknesses on surface heat budget even when SIC changes are small. To set context, we also compare results from the wintertime high latitude Arctic to other seasons (fall) and regions that are undergoing rapidly changing SIC and associated changes in surface heat fluxes due to open water formation.

## 2 Models and Analysis

### 2.1 CESM1-LE

We use the Community Earth System Model version 1 Large Ensemble (CESM1-LE; Kay et al., 2015) to explore relationships between Arctic wintertime conductive heat fluxes and sea ice and snow thickness fields. The CESM1-LE consists of 40 simulations forced with historical forcing from 1920-2005, and then the Representative Concentration Pathway 8.5 (RCP8.5) forcing from 2005-2100 (the no-mitigation scenario with a top of the atmosphere radiative forcing of  $8.5 \text{ W/m}^2$  by 2100; Meinshausen et al., 2011). The sea ice model component (CICE; Hunke et al., 2015) in the CESM1 uses a sub-gridscale ice thickness distribution (ITD) in which thermodynamics are calculated over 5 discrete sub-gridcell thickness categories with minimum thicknesses of 0., 0.64, 1.39, 2.47 and 4.57 meters. The presence of the ITD influences both the mean climate state and climate feedbacks (Holland et al., 2006). The simulated ITD and sea ice concentrations within each category evolve through ice growth and melt, ridging due to mechanical forcing, and ice transport (e.g. Thorndike et al., 1975). The resulting concentrations of sea ice can range from 0 to 100% (although values of 100% are rare due to lead formation) in the discrete thickness layers. Snowfall can accumulate on sea ice and be affected by snow melt, ice ridging and transport. Effectively this means that a different snow depth is present across the different ice thickness categories. Ice-atmosphere fluxes are calculated separately in each sea ice thickness category, weighted by the concentration in each category, and passed as grid-cell means to the flux coupler for use in the atmospheric model. CICE uses a multi-layer thermodynamic scheme (Bitz and Lipscomb, 1999; “BL99”) that includes the effects of a prescribed vertical salinity profile. Comparisons with the Pan-Arctic Ice Ocean modelling and Assimilation system (PIOMAS; Zhang & Rothrock, 2003) sea ice thickness reanalysis product show that the CESM1-LE and PIOMAS agree well for both summer and winter rates of sea ice volume change (Labe et al., 2018a). CESM1-LE and PIOMAS also tend to agree on regional mean thicknesses and variabilities throughout much of the Arctic with the

exception of the Canadian Archipelago and coastal Greenland, where the CESM1-LE overestimates sea ice volumes compared to PIOMAS (and PIOMAS underestimates volumes compared to buoy and submarine data).

## 2.2 0-layer thermodynamic conductive heat-flux model

100 Not all thermodynamic variables for individual ice thickness categories were saved as part of the CESM1-LE output. In order to disentangle the relative influences of sea ice and snow thicknesses and their distributions, we use the available CESM1 output along with the 0-layer thermodynamic model of Semtner (1976) to estimate the conductive heat flux. This simple 0-layer model – developed originally to minimize computational costs associated with ice thickness calculations in climate models – assumes a linear temperature gradient through the sea ice and snow, and that the conductive heat flux through the ice+snow  
105 layer is:

$$F_{\text{cond}} = \frac{K_s(T_b - T_s)}{h_s + K_s \left( \frac{SIT}{K_i} \right)} \quad \text{Eq. 1}$$

where

110  $K_s, K_i$  = snow and ice conductivities of heat ( $0.3 \text{ Wm}^{-1}\text{degK}^{-1}$ ,  $2.0 \text{ Wm}^{-1}\text{degK}^{-1}$ )

$h_s, SIT$  = snow and ice thicknesses

$T_b, T_s$  = temperatures at the bottom (ocean-ice) and surface (ice-atmosphere) of the ice

The conductive heat flux reduces to:

115

$$F_{\text{cond}} = \frac{K_i \Delta T}{h_{\text{eff}}} \quad \text{Eq. 2}$$

where

$\Delta T = T_b - T_s$

120  $h_{\text{eff}} = (SIT + (K_{\text{ratio}} * h_s))$  is a measure of the effective thickness from an insulating perspective, with

$K_{\text{ratio}} = K_i / K_s$

In the Arctic winter, surface temperatures are cold - well below the melting point of ice and snow - and the net surface energy budget (the sum of the net short- and longwave radiation, and sensible and latent heat fluxes) in ice covered regions is balanced

125 by the conductive heat flux from the ocean through the sea-ice and snow. Where open water is present, such as leads in the sea  
ice, direct atmosphere-ocean exchange also occurs. Climate simulations that prescribe constant sea ice thickness such as those  
used in Atmospheric Model Intercomparison Project (AMIP) and most of the Polar Amplification Model Intercomparison  
Project (PAMIP; Smith et al., 2019) experiments only allow for changes in conductive heat fluxes to occur through changes  
130 in temperatures and possibly through snow depth changes resulting from changing snowfall. This results in inaccurate  
estimates for changes in surface heat fluxes (and thus also temperatures) which can be quite sizable and of the wrong sign. For  
example, in response to 20°C surface warming, changes in conductive heat fluxes from a “typical” 20<sup>th</sup> Century mid-Arctic  
ocean (with 2.0 m thick ice covered by 0.1 m thick snow with a surface to base  $\Delta T$  of 40°C) will be roughly halved if SIT and  
snow thicknesses are held constant but doubled if the ice thins to 0.5m with 0.02 m of snow (e.g. Table 1). In CESM2 PAMIP  
(100 member ensembles comparing present-day and future changes from 1850s; Smith et al., 2019; Sun et al., 2022) and AMIP  
135 (10-member ensembles investigating historical changes; Hurrell et al., 2008; Simpson et al., 2020) simulations in which ice  
thickness is prescribed and unchanging, net surface heat fluxes increase outside of sea ice covered areas but decrease over sea  
ice covered areas as the surface temperatures warm (Figure 1). For reference, Arctic sea ice volume decreased by ~66% from  
the mid-twentieth century to the present (Kwok, 2018; Lindsay and Schweiger, 2015). Thus, keeping SIT constant during this  
period, in direct contrast to observations, artificially introduces errors in surface heat flux calculations – and thus also  
140 temperature changes over sea ice covered regions. These differences in wintertime conductive heat fluxes are not insignificant  
contributions to the surface energy budget (e.g., Huwald et al., 2005). Notably, many simulations that have been used to  
diagnose Arctic Amplification rely on AMIP-type simulations which specify the fractions of open water and sea ice yet neglect  
ice thickness changes (e.g. Smith et al., 2019). Even when ice thickness anomalies are applied (e.g. Lang et al.2017; Labe et  
al. 2018b; Sun et al., 2017; Smith et al., 2019), they are specified for a mean gridcell value, missing the potential role of ice  
145 thickness heterogeneity which could be important given that the conductive flux has a non-linear dependence on ice and snow  
thickness. AMIP and PAMIP protocols do not specify snow depths as part of the sea ice boundary conditions and different  
modelling systems use different approaches to modifying (or not) the snow over sea ice in perturbed climate simulations.

### 2.3 Analysis

We are interested in wintertime Arctic heat fluxes during a period when wintertime central Arctic SIC remain relatively high  
150 and changing sea ice and snow thickness will play a dominant role in changing surface fluxes. Thus, we focus initially on  
1950-2070 and on the month of February to explore in detail relationships between conductive heat fluxes, snow and sea ice  
thicknesses, and thickness distributions. Timeseries presented are area averages over the Arctic Ocean (68°-90°N from 100°-  
243°E, and 80°-90°N elsewhere – see inset in Figure 2b), thereby reducing the influence of changes in winter sea ice  
concentrations (SIC) that are seen in the simulations during this time period in the neighboring regions. Changes in conductive  
155 heat fluxes due to thinning sea ice dominate the surface heat budget until the sea ice thins enough to subsequently start  
retreating, exposing open ocean. To highlight this contrast between ice covered regions and time periods, and those with  
increasing open water areas, we also show timeseries from the Kara and Barents seas (see inset in Figure 5) and some results

from October when SIC are already changing rapidly at the beginning of the 21<sup>st</sup> Century. Our regional definitions are those used by the National Snow & Ice Data Center ([www.nsidc.org](http://www.nsidc.org)) and discussed in Parkinson and Cavalieri (2012), Cavalieri and Parkinson (2008), and Parkinson et al. (1999).

We then explore the relative and changing importance of sea ice conductive heat fluxes to the total surface heat fluxes in a warming world in the cold season (October through March) in the 21<sup>st</sup> century. In the high-latitude Arctic winter, when there is no solar radiation and the surface air temperature is well below the freezing point, the net surface heat flux over the sea ice (total surface short- and longwave radiation, and sensible and latent heat fluxes) is balanced by the conductive heat flux through the ice and snow. In regions not 100% covered by sea ice, there will also be heat flux from the ocean to the atmosphere. The relative contributions of heat fluxes from ocean and sea ice areas will change both as ice and snow thin, and as sea ice concentrations decrease. We ask how these relative contributions change in winter months as the projected climate warms and compare ice-covered regions with two regions (Barents Sea and Kara Sea) that are experiencing significant wintertime sea ice concentration losses from 2010-2070.

We also assess the role of sub-gridcell sea ice thickness distributions in simulated conductive heat fluxes. Model output of conductive heat flux is available on a gridcell level and is computed as the area weighted average of the sub-gridcell conductive heat fluxes. This explicitly accounts for changing ice and snow thicknesses, surface temperatures, and areal concentrations for the different ice thickness categories. Although sub-gridcell conductive heat flux information that would enable us to directly relate changes in the sub-gridcell ITD to the net flux was not saved and is not available, sub-gridcell ice and snow thicknesses are available. Comparisons between the model net gridcell conductive heat fluxes to those calculated using the sub-gridcell ice and snow thicknesses, the gridcell surface temperatures and the 0-layer model demonstrate that the 0-layer model gives a good approximation for this analysis (Supplemental material). We then compare the model conductive heat fluxes which account for the subgridscale ice thickness distribution (CESM1-LE) with those calculated from the gridcell mean SIT and snow thicknesses using the 0-layer model (“MNthick”) to investigate the influence of snow and sea ice heterogeneity on conductive heat flux calculations.

### **3 Results**

#### **3.1 Sea ice and snow thicknesses**

Over the Arctic Ocean, simulated February surface temperatures and conductive heat fluxes, which are equivalent to the ice-atmosphere heat exchange, increase by  $\sim 8^{\circ}\text{C}$  and  $9 \text{ W/m}^2$  between the late 20<sup>th</sup> century and 2070 in the CESM1-LE (Figure 2a). The turbulent heat flux exchange between the ocean and the sea ice increases during this time as well – however by less than  $1 \text{ W/m}^2$  and therefore is not a dominant contribution to the increased net surface heat exchange. Increases in conductive heat flux are driven by decreases in sea ice and snow thickness, since the increase in surface temperatures alone would result

190 in a decrease in conductive heat fluxes (Equation 2). During this time, sea ice concentrations in the Arctic Ocean remain high  
yet sea ice and snow thin dramatically (Figure 2b), with a mean total effective thickness ( $h_{\text{eff}}$ ) decreasing from a peak near 6  
m in the 1970s to 1.5 m by 2070 (Figure 2c). Snow thicknesses averaged over the Arctic Ocean region are typically less than  
0.5 m thick – much thinner than sea ice - however snow, and changes in snow, make significant contributions to both the total  
effective thickness and the changes in total effective thickness, due to the much larger insulating capacity of snow (Figure 2c).  
195 The decreasing wintertime snow depths over the 21<sup>st</sup> Century in the CESM1-LE are due primarily to sea ice forming later in  
the fall, which in turns leads to a later start of accumulation of snow on the sea ice (e.g. Webster et al. 2014; Webster et al.  
2018; Webster et al., 2020). This mechanism has also been found in projections of snow on sea ice (Hezel et al., 2012) and in  
observations (Webster et al. 2014; Webster et al. 2018). In addition, as the temperatures warm, the rain/snow seasons  
increase/decrease (e.g. Webster et al., 2020).

200 Conductive heat fluxes increase first over the East Siberian and Chukchi seas (Figure 3). By the 2050s, increases in  
conductive heat fluxes of 9-12 W/m<sup>2</sup> are seen not only in the Chukchi and East Siberian seas, but also extending into the  
Beaufort Sea and the Central Arctic Ocean. Surface temperature increases likewise show the earliest and greatest increases on  
the Pacific side of the Arctic Ocean. However, by the 2050s the areas of greatest warming (>10°C) are present over  
comparatively larger sections of the Arctic Ocean, Beaufort Sea and extend as far as northern Greenland. Sea ice concentrations  
205 remain above 95% in the Arctic ocean even by the 2050s. As such, changes in heat fluxes from the relatively warmer surface  
to the colder atmosphere primarily result from thinning sea ice and snow rather than increases in open water (see section 3.2).  
Changes in sea ice thicknesses in the CESM1-LE tend to be largest from the Canadian Archipelago, across the Central Arctic  
ocean and on to the East Siberian sea (Supplemental material), whereas changes in snow thickness are greatest near the  
Canadian Archipelago and northern and eastern Greenland. Changes in both sea ice and snow thicknesses are important  
210 contributors to the changes in effective thickness (Figure 3). Although snow depth changes are small compared to changes in  
SIT, they contribute 40% or more to the changes in effective thicknesses from the central Arctic Ocean to the Canadian  
Archipelago, Greenland and into the Atlantic sector of the Arctic ocean (Figure 3 and Supplemental material). It is important  
to note that changes in conductive heat fluxes during this time are mitigated by changes in surface temperatures: the roughly  
13° surface warming over this period would lead to ~5 W/m<sup>2</sup> decrease in conductive heat flux if the sea ice and snow did not  
215 thin (and as they do in the AMIP and PAMIP atmosphere only runs when SITs are held constant - e.g., Figure 1).

### 3.2 Relative contributions of conductive heat flux changes to total surface heat flux changes in a warming climate

Changes in conductive heat fluxes due to thinning sea ice dominate the surface heat budget until the sea ice thins enough to  
subsequently start retreating, whereupon the surface heat flux quickly becomes dominated by fluxes from exposed open water  
220 (Figures 4 and 5). Ensemble mean February net surface heat fluxes over the Arctic ocean increase modestly from the 1950s to  
the 2010s (~3-6 W/m<sup>2</sup>), then by ~10-18 W/m<sup>2</sup> by the 2050s. Arctic ocean SICS remain above 98% - increases in surface heat  
flux are primarily due to changes in snow and ice thicknesses, with open water areas contributing less than 10-25% to the net  
surface heat flux budget. In contrast, outside of the ice covered areas, increases in surface heat fluxes are larger than 25 W/m<sup>2</sup>

and predominantly due to fluxes from open water. In February, these areas expand from the Sea of Okhotsk and the Bering, Kara and Barents seas in the 2010s to include most of the Arctic ocean by the end of the 21<sup>st</sup> Century. Rates of surface temperature warming reflect this as well – with the highest February Arctic Amplifications occurring initially over the Chukchi and East Siberian Seas, where sea ice is thinning, over the Barents and Kara Seas by the 2050s, and finally over large sections of the Arctic Ocean as SICs fall by the 2090s (Figure 4). These patterns of relative contributions of sea ice and ocean to the net surface heat fluxes, and corresponding rates of AA, are also seen in the fall (October; Supplementary material), when observed AAs are highest (e.g. Chung et al., 2021) and underscore the transient and seasonal nature of AA which may increase in regions experiencing sea ice loss before decreasing again after becoming ice-free (e.g. Holland & Landrum, 2021). Regionally averaged timeseries show how contributions from open ocean water to the net surface heat fluxes tend to be greater than those from ice once SICs fall below ~90% - highlighting how changes in surface heat fluxes will be dominated by those over sea ice (due to thinning sea ice and snow) until sea ice itself starts retreating (Figure 5). Variability in heat fluxes from the ocean tend to be very high compared to those from sea ice, particularly in the Barents and Kara Seas.

### 3.3 Sea ice and snow thickness distributions

Given the nonlinear response of the conductive heat flux to ice and snow thickness, the changing distribution of ice at the sub-gridcell level may play an important role. We investigate the influence of thickness distributions on conductive heat fluxes by calculating conductive heat fluxes using the Semtner 0-layer model, daily mean sea ice and snow thicknesses over the ice-covered areas in each grid cell along with daily gridcell average surface temperatures (“MNthick”), and then averaging over the month of February. Relative to an estimate of the fluxes computed by the full model (CESM1-LE), the MNthick conductive heat fluxes underestimate heat fluxes throughout the Arctic Ocean (Figure 6a, and Supplemental material). Ensemble mean Arctic Ocean average conductive heat flux is underestimated by ~6-9 W/m<sup>2</sup> using MNthick (Figure 6). This highlights the importance of resolving thin ice and snow within the subgridscale ice thickness distribution.

Differences between these winter-time conductive heat fluxes throughout the Arctic basin are larger in the beginning of the 21<sup>st</sup> century (by ~35%) when considerable thick ice is present. Discrepancies between MNthick conductive heat flux estimates and CESM1-LE are reduced by the 2070s (to ~16%) when almost all the February sea ice in the Arctic Ocean has thinned considerably to less than 1m over the Arctic ocean and the ITD lies within the two thinnest sea ice categories (Figure 6b). Although grid-cell average thicknesses lead to an underestimation of mean conductive heat fluxes, they result in an overestimation in the changes in conductive heat fluxes (by ~ 36% by 2070; Figure 6a) and thus influence feedbacks in the warming climate.

#### 4 Discussion and Conclusions

255 This analysis has important implications for atmosphere-only simulations and reanalysis products that require specified sea ice concentrations, sea ice thicknesses and snow depths for boundary conditions. These simulations typically prescribe changes in sea ice concentration but neglect changes in ice and snow thickness. The sea ice concentration changes lead to large changes in surface albedos and direct ocean-atmosphere heat fluxes as more ocean water is exposed to the atmosphere. However, by neglecting changes in ice and snow thickness, the changing insulating effect of sea ice is missing. As the climate warms, 260 changing winter Arctic surface heat fluxes will be dominated by this insulating effect and resulting changes in conductive heat fluxes until the SICs decrease enough such that direct ocean-atmosphere heat fluxes become more important. In the CESM1-LE, with changing subgridscale ice and snow thicknesses, conductive heat fluxes contribute over half of the Dec-Mar surface heat fluxes until 2050-2070 (not shown). Atmosphere only simulations that consider only changes in sea ice concentrations and ignore changes in sea ice and snow thicknesses simulate decreasing conductive heat fluxes – the winter atmosphere in 265 high SIC regions gains *less* heat from the surface under climate warming. When changing ice thicknesses and snow depths are accounted for, conductive heat fluxes increase and the atmosphere gains **more** heat from the surface. In the CESM1-LE, Arctic basin conductive heat flux increases by ~8-10 W/m<sup>2</sup> from 2000 to 2070 as winter SIC remain above 95%.

Sea ice and snow exhibit high spatial heterogeneity and climate models often account for this through the inclusion of a 270 subgridscale ice thickness distribution within their sea ice treatment. This heterogeneity of both sea ice and snow fields impacts conductive heat fluxes and thus the projected changes in the net surface heat flux. Whereas most climate models participating in the most recent Coupled Model Intercomparison Project (CMIP6) employ sea ice models with sub grid-scale sea ice thickness distributions (e.g. Keen et al., 2021), atmosphere-only simulations (for example AMIP and PAMIP style simulations) calculate sea ice thermodynamics over only gridcell mean sea ice and snow thicknesses. This will underestimate mean 275 wintertime conductive heat fluxes and, in the PAMIP simulations that allow thickness to change, will overestimate changes in conductive heat fluxes as the ice thins. These differences can be significant – in the CESM1-LE mean conductive heat fluxes calculated using grid-cell mean thicknesses lead to an underestimation of ~16-35% in mean values and an overestimation of up to ~36% in the changes in conductive heat fluxes in the wintertime Arctic basin where SIC remain above 95%.

280 Snow is a much more effective insulator than sea ice and plays important roles in sea ice mass budgets and climate feedbacks. Snow distributions on sea ice remain, however, an area of large uncertainty and potential errors in both climate model simulations and reanalysis products. PAMIP protocols and reanalysis products use either very simplified snow (accumulations only through precipitation) or non-existent snow routines, with resultant flux estimates that show large wintertime heat flux biases when compared to the recent Norwegian young sea-ICE campaign (N-ICE2015) observations (e.g. Bromwich et al., 285 2018; Graham et al., 2017). Yet snow – highly reflective and highly insulating - plays an outsized role in Arctic heat budgets. Reanalysis products show consistent warm bias in winter sea ice surface temperatures (e.g. Batrak & Muller, 2019; Graham

et al., 2017; Graham et al., 2019; Jakobson et al., 2012; Lindsay et al., 2014), with recent work attributing this to misrepresentation of snow on sea ice (Batrak & Müller, 2019).

290 Snow and sea ice thicknesses and distributions in the CESM1-LE are roughly equally important contributors to wintertime  
conductive heat fluxes. Snow depth distributions in the CESM1-LE show similar patterns compared to observations across the  
Arctic Basin, although simulated snow depths tend to be more evenly distributed and thicker than observed (Webster et al.,  
2020). Snow thicknesses in the most recent version of CESM – the CESM2 – tend to be underestimated and have low  
variability compared to observations. These differences between simulations are due largely to differences in precipitation and  
295 the mean sea ice state in these two models (Webster, et al., 2020). Discrepancies between simulations and observations,  
however, are not well understood and suggest that future collaborative work to test and improve snow distributions in the  
modeling environment would be important for increasing our understanding of Arctic climate and predicting snow impacts in  
a warming climate.

300 The results presented here are from a large ensemble of simulations from one climate model. Recent contributions from  
multiple modelling centers to the CMIP6 suggest that the sea ice components in climate models are responding consistently to  
external forcing (e.g. Keen et al, 2021) and our results are not expected to change fundamentally with different climate models  
although the timing may differ based on the mean ice state. In the CESM1-LE SICs remain above 98% in the high latitude  
Arctic Ocean until the end of the 21<sup>st</sup> Century and this timing will differ depending on the initial mean ice state and transient  
305 response in a given model. For example, the most recent version of the model, the CESM2 includes many changes all model  
components, and Arctic sea ice in the CESM2 tends to be thinner, less extensive and less persistent than in the CESM1-LE  
(DeRepentigny et al., 2020).

These results highlight the transient nature of the influences of SIT, snow thicknesses, and their distributions on Arctic  
310 wintertime surface heat budgets. The thermodynamics of sea ice are dependent on the mean ice state (e.g. Massonnet et al.,  
2018) – and this has important implications not only for sea ice evolution in a changing world, but also surface heat fluxes in  
ice covered areas. Models with a relatively thin sea ice mean state will have higher errors in changes in surface heat fluxes  
depending on whether they use grid-cell mean SITs or heterogeneous fields. Sea ice and snow on sea ice are important  
components of polar climate thermodynamics and their dynamic and heterogeneous nature – although complicated – play  
315 important roles in surface heat budgets.

### **Code and Data availability**

All analysis and figures were completed using the NCAR Command Language (The NCAR Command Language v.6.6.2  
(UCAR, NCAR, CISL and TDD,2019); <https://doi.org/10.5065/D6WD3XH5>). The scripts used to perform the analysis and

generate the figures in this manuscript are available on GitHub  
320 ([https://github.com/llandrum/Cryosphere\\_SeaIce\\_Snow\\_Thicknesses\\_ArcticHeatFlux](https://github.com/llandrum/Cryosphere_SeaIce_Snow_Thicknesses_ArcticHeatFlux)) and archived in Zenodo (Landrum, 2021).  
The CESM-LE data are freely available from the following link: <http://www.cesm.ucar.edu/projects/community-projects/LENS/> (last access: 7 April 2020, Deser and Kay, 2020; Kay et al., 2015).

### **Author contribution**

325 LL and MMH formulated the research goals and questions. LL made the figures and performed the analysis with input from  
MMH. LL prepared the manuscript with contributions from MMH.

### **Competing interests**

The authors declare that they have no conflict of interest.

### **Acknowledgments**

330 We acknowledge funding from NSF-OPP 1724748. We also acknowledge the CESM Large Ensemble Community Project  
and supercomputing resources (doi:10.5065/D6RX99HX) provided by the Climate Simulation Laboratory at NCAR's  
Computational and Information Systems Laboratory, sponsored by the National Science Foundation and other agencies.  
We thank Alice DuVivier for providing the daily CESM1-TS data so that we could compare 0-layer to multi-layer model  
estimates of conductive heat fluxes

### Figure captions

480 **Figure 1.** Changes in ensemble mean February net surface heat flux (netSHF; a-d) and surface temperatures (TS; e-h) for CESM2 PAMIP (a-c, e-g) and AMIP (d, h). PAMIP differences are from an 1850 pre-industrial control run where both SSTs and SICs are specified at 1850 levels. Differences from the PI are shown for PAMIP experiments with present-day SSTs and SICs (pdSST-pdSIC; a,e); present-day SSTs and future SICs (“pdSST-futArcSIC; b, f), and future SSTs and SICs (futSST-futArcSIC; c, g). AMIP simulations are from a 10-member ensemble and differences shown are ensemble mean of the final  
485 decade (2005-2014) minus the first decade (1950-1959) of the simulations. The 98% SIC contour is shown in black.

**Figure 2.** CESM1-LE February area-averaged Arctic Ocean (a) surface temperatures, turbulent ocean-sea ice heat fluxes and conductive heat fluxes; (b) SIC, SIT and snow thicknesses ( $h_s$ ); and (c) effective snow thickness ( $K_{ratio} * h_s$ ), and effective total thicknesses (heff). Ensemble means are show in the solid lines, ensemble ranges in opaque polygons. Arctic Ocean region is  
490 shown in the map insert in the middle panel.

**Figure 3.** February decadal mean changes (from 1950-1959) in surface temperatures (a, d), conductive heat fluxes (b, e), and effective sea ice + snow thickness (heff; e, f) for the 2010s (a, b, c) and 2050s (d, e, f). The 98% SIC for each decade is shown by the thick black contour. Stippled areas in the effective thickness (heff) change figures (c, f) indicate regions where changes

495 in effective snow thickness ( $K_{\text{ratio}} * h_s$ ) account for 40% or more of the changes in the total effective thickness ( $heff = SIT + K_{\text{ratio}} * h_s$ ).

**Figure 4.** February decadal mean changes (from 1950-1959) in Arctic Amplification ( $\Delta TAS / \Delta TAS_{\text{global}}$ ; a, e, i), net surface heat fluxes (b, f, j), sea ice contribution to surface heat fluxes (c, g, k), and ocean contributions to surface heat fluxes (d, h, l) for the 2010s (a, b, c, d), the 2050s (e, f, g, h) and the 2090s (i, j, k, l). The 98% SIC for each decade is shown by the thick black contour.

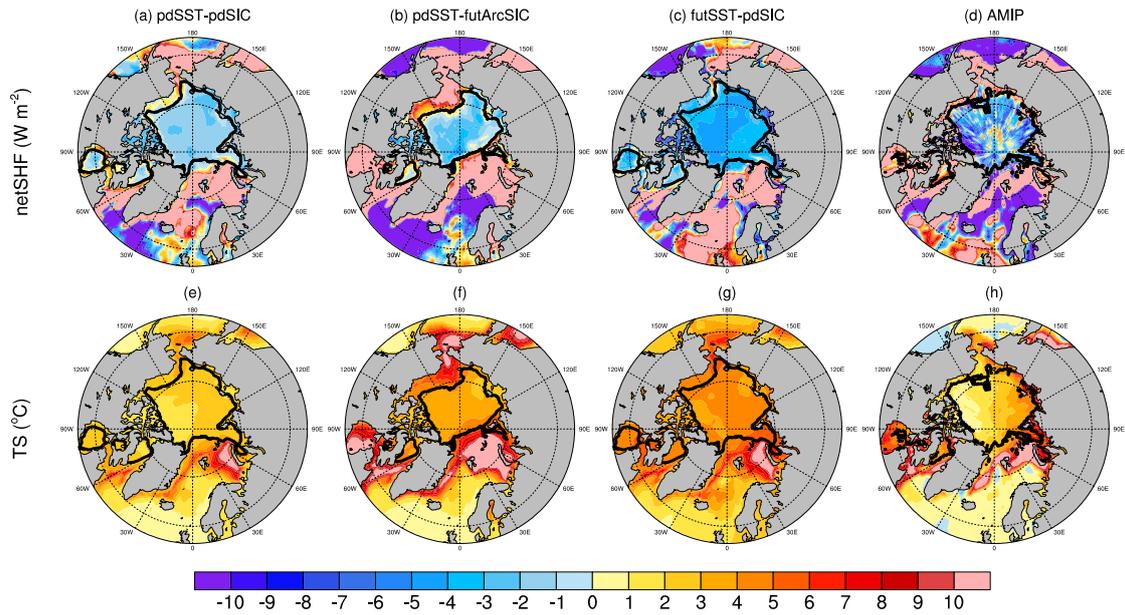

**Figure 5.** CESM1-LE area-averaged anomalies (from 1950-1959 ensemble mean) for sea ice and ocean contributions to net surface heat fluxes (left axis), and sea ice concentrations (right axis) for February (left column) and October (right column) Arctic Ocean (top), Kara (middle) and Barents (bottom) seas. Ensemble means are shown in the solid lines, ensemble ranges in opaque polygons. Geographic areas are shown in inset at bottom.

**Figure 6.** CESM1-LE February area-averaged Arctic Ocean (a) mean conductive heat fluxes from the model output (“CESM1-LE”; dark blue) and calculated from mean ice and snow thicknesses (“MNthick”; light blue), and the ratio of MNthick to CESM1-LE (red) and (b) sea ice areas by thickness category as well as total sea ice area (dark blue). Ensemble means are shown in the solid lines, ensemble ranges in opaque polygons. The solid black line in top panel indicates a MNthick:CESM1-LE conductive heat flux ratio of 0.75 for reference.
