## Abstract

Ice shelves play a key role in the dynamics of marine ice sheets, by buttressing grounded ice and limiting rates of ice flux to the oceans. In response to recent climatic and oceanic change, ice shelves fringing the West Antarctic Ice Sheet (WAIS) have begun to fragment and retreat, with major implications for ice sheet stability. Here, we focus on the Thwaites Eastern Ice Shelf (TEIS), the remaining pinned floating extension of Thwaites Glacier. We show that TEIS has undergone a process of fragmentation in the last five years, including brittle failure along a major shear zone, formation of tensile cracks on the main body of the shelf, and release of tabular bergs on both eastern and western flanks. Simulations with the Helsinki Discrete Element Model (HiDEM) show that this pattern of failure is associated with high backstress from a submarine pinning point at the distal edge of the shelf. We show that a significant zone of shear upstream of the main pinning point developed in response to the rapid acceleration of the shelf between 2002 and 2006, seeding damage on the shelf. Subsequently, basal melting and positive feedbacks between damage and strain rates weakened TEIS, allowing damage to accumulate. Thus, although backstress on TEIS has likely diminished through time as the pinning point has shrunk, accumulation of damage has ensured that the ice in the shear zone has remained the weakest link in the system. Experiments with the BISICLES ice sheet model indicate that additional damage to or unpinning of TEIS are unlikely to trigger significantly increased ice loss from WAIS, but the calving response to loss of TEIS remains highly uncertain. It is widely recognised that ice shelf fragmentation and collapse can be triggered by hydrofracturing and/or unpinning from ice shelf margins or grounding points. Our results indicate a third mechanism, *backstress triggered failure*, that can occur if and when an ice shelf is no longer able to withstand stress imposed by pinning points. In most circumstances, pinning points are essential for ice shelf stability, but as ice shelves thin and weaken the concentration of backstress in damaged ice upstream of a pinning point may provide the seeds of their demise.

## 1 1. Introduction

2  
3 Ice shelves play a key role in the dynamics of marine ice sheets. By transmitting resistive  
4 stresses from lateral or basal pinning points to the grounding line, ice shelves buttress  
5 grounded portions of the ice sheet and constrain ice flow (e.g. Doake et al., 1998; DuPont and  
6 Alley, 2005). If buttressing is reduced or lost following the retreat or disintegration of ice  
7 shelves, tributary glaciers can accelerate and increase ice flux to the ocean (Scambos et al.,  
8 2004). Accelerated ice discharge may be temporary and reversible, but modelling studies  
9 indicate that in some circumstances (e.g. where the bed is steeply retrograde) ice-shelf break-  
10 up may initiate sustained loss of grounded ice and irreversible retreat through the marine ice  
11 sheet and marine ice shelf instabilities (Schoof, 2012; Sun et al., 2020; DeConto et al., 2021;  
12 Bassis et al., 2021). Large areas of the West Antarctic Ice Sheet are vulnerable to this process,  
13 particularly Thwaites Glacier and Pine Island Glacier in the Amundsen Sea Sector (Scambos et  
14 al., 2017).

15  
16 In response to recent climatic and oceanic change, the geographical extent of ice shelf retreat  
17 and disintegration has spread south and westward from the Antarctic Peninsula into West  
18 Antarctica (Cook and Vaughan, 2010; Liu et al., 2015). If the response of WAIS to a variety of  
19 climate change scenarios is to be predicted with confidence, understanding the processes  
20 affecting ice shelf stability is a matter of urgency (Fox-Kemper et al., 2021). The prominent role  
21 of melt pond drainage and hydrofracturing in the demise of Larsen B in 2002 (Scambos et al.,  
22 2003) has focused attention on surface melting as a trigger for ice-shelf disintegration (e.g.  
23 Robel and Banwell, 2019; Lai et al., 2020). Recent observations, however, indicate that ice-shelf  
24 retreat and disintegration can occur in the absence of surface melt, if basal melting causes ice  
25 to lose contact with lateral or sea-floor pinning points. Recent examples include major rifting  
26 and calving from Pine Island Glacier following weakening of lateral pinning points (Arndt et al.,  
27 2018; Lhermite et al., 2020) and fragmentation of the Thwaites Western Ice Tongue (TWIT; Fig.  
28 1) following progressive loss of a sea-floor pinning point (Tinto and Bell, 2011; Miles et al.,  
29 2020).

30  
31 In this paper, we focus on the Thwaites Eastern Ice Shelf (TEIS), the remaining pinned floating  
32 extension of Thwaites Glacier. TEIS is currently pinned at its distal end by a sea-floor ridge (Fig.  
33 1), but rates of ice thinning over this pinning point suggest that complete unpinning could occur  
34 in less than one decade (Alley et al., 2021; Wild et al. 2021). Here we use a high-frequency time  
35 series of Sentinel-1 imagery to show that within the last 5 years it has transitioned from an  
36 intact ice shelf to a highly fragmented state. The ongoing acceleration of parts of the ice shelf  
37 suggest the crossing of a threshold from stable to unstable. Our simulations with the Helsinki  
38 Discrete Element Model (HiDEM) show a distinct fracture pattern that supports this threshold-  
39 crossing behaviour occurring due to the failure of weakened ice in response to stresses  
40 associated with the pinning point and not due to progressive unpinning. Pinning points,  
41 therefore, are not necessarily always a stabilising factor for ice shelves, but instead may have a  
42 destabilising effect when ice around them is sufficiently weakened. Finally, we use the ice-sheet  
43 model BISICLES to explore the possible near-term consequences of damage evolution, shelf  
44 thinning and decoupling of TEIS from the pinning point. The recent behaviour and imminent  
45 break-up of TEIS has important implications for both ice shelf stability and the effectiveness of  
46 buttressing from intact and fragmented ice shelves.

## 1 **2. Methods**

2

### 3 **2.1 Observations**

4 We use satellite data to monitor surface features which indicate the evolution of surface and  
5 basal fractures, and to derive surface velocity fields to monitor change in ice flow rate and  
6 patterns of surface strain. The main source of satellite data is Sentinel-1 (image resolution  
7  $\sim 10\text{m}$ , velocity product resolution  $\sim 100\text{m}$ ), but we also use velocity products from MODIS  
8 (velocity product resolution  $\sim 500\text{m}$ ; Alley et al., 2021), MEaSURES (velocity product resolution  
9  $\sim 1\text{km}$ ; Mougnot et al., 2017) and ITS-LIVE (velocity product resolution  $\sim 240\text{m}$ , Gardner et al.,  
10 2019) to provide historical context.

11

12 Surface velocity fields are derived from Sentinel-1 Interferometric Wide (IW) Mode using  
13 standard feature/speckle tracking procedures (e.g. Luckman et al., 2015). We employ the whole  
14 satellite data archive since 2014 and combine velocity maps by averaging following a spatial  
15 filter based on signal-to-noise ratio and local variability. We present results of individual  
16 velocity maps on key dates and mean velocity products on an annual, quarterly or monthly  
17 basis to assess the development of speed and strain. We use a combination of 6-day and 12-  
18 day Sentinel-1 image pairs from the available archive and our feature tracking window size is  
19  $416 \times 128$  which equates to  $\sim 1\text{km}$  in range and azimuth. We sample the velocity field at  $50 \times 10$   
20 pixels before geocoding to the Antarctic Polar Stereographic projection (EPSG:3031) at  $100\text{m}$   
21 resolution using the REMA mosaic DEM (Howat et al., 2019) gap-filled by Bedmap2 surface  
22 topography data (Fretwell et al., 2013). Strain rates are derived from selected 6-day pair  
23 velocity maps with high coherence and low noise, and are calculated in a  $3 \times 3$  neighbourhood  
24 for optimum resolution.

25

### 26 **2.2 Modelling experiments**

27 Modelling experiments were conducted with the Helsinki Discrete Element Model (HiDEM) and  
28 the BISICLES ice sheet model, to investigate fracture processes underway at TEIS and ice-sheet  
29 dynamic response to the ice shelf's evolution, respectively.

30

31 HiDEM is a brittle-elastic fracture model that can be used to simulate ice fracture and calving  
32 processes by representing ice as arrays of particles linked by breakable elastic beams (Åström  
33 et al., 2013). Particles are stacked together in a hexagonal close-packed lattice to form a 3D  
34 domain representing observed ice geometries. The version used in this study (HiDEM2.0) was  
35 developed by JAÅ and Fredrik Robertsen at the CSC IT Center for Science, Finland, with data  
36 structures and parallelisation scheme optimized for effective computation. On a modern HPC  
37 system HiDEM2.0 can compute  $10^6$  timesteps for  $10^8$  particles in about 24 hours, with a  
38 timestep length of 0.001 seconds. This is 1-2 orders of magnitude faster than older versions of  
39 HiDEM, allowing simulations of much larger domains with smaller particle sizes.

40

41 Five parameters determine the bulk tensile and shear strength of the ice: particle size, beam  
42 width to particle diameter ratio, beam tensile breaking strain, maximum beam endpoint  
43 bending angle, and density of randomly-distributed pre-broken beams (damage). In the  
44 simulations reported here, we use a particle size of  $40\text{m}$ , a beam width to particle diameter  
45 ratio of 0.6, tensile breaking strain of 0.0005, and a maximum bending angle of 0.03 radians,  
46 values that were calibrated against observed fracture and calving patterns on the Greenlandic  
47 glacier Sermeq Kujalleq (Jakobshavns Isbrae). The calibration was focused at Sermeq Kujalleq  
48 given the glacier's large ice thickness and the availability of remotely-sensed observations of  
49 calving.

1 The HiDEM model domain incorporates the entire area of TEIS and extends 20 to 30 km  
2 upstream of the grounding line. The domain is based on BedMachine v2 (Morlighem, 2020),  
3 which incorporates the REMA mosaic ice-surface elevation DEM (Howat et al., 2019),  
4 hydrostatic ice thickness for the fully floating regions, and recent updates to the Thwaites  
5 Glacier bed and adjacent seafloor (Jordan et al., 2020). The glacier bed DEM does not  
6 incorporate recent data on the TEIS pinning point presented by Wild et al. (2021); the  
7 implications of this omission are discussed below.

8 The model domain was adjusted in a short (2.5 d) surface relaxation in Elmer/Ice, to ensure  
9 that the ice shelf base near the grounding line was at equilibrium with stresses in the ice, as  
10 well as buoyant forces. The extent of the pinned ice, which consists of two separate pinning  
11 regions, was unchanged over the relaxation period. The surface height changed minimally and  
12 the height above floatation over the pinned regions (approximately 20 to 30 m) is comparable  
13 to values shown by Wild et al. (2021). Any differences are negligible considering the 40 m  
14 particle size used in the HiDEM simulations. Ice viscosity and basal resistance were then  
15 estimated following the serial inversion workflow described in Gladstone et al. (in prep) using  
16 MEaSUREs v.2 velocity data (Rignot et al., 2011a, b; Mouginot et al., 2012, 2017). The region of  
17 the REMA mosaic covering TEIS is based on data acquired in 2013-2014 and the velocity data  
18 are from 2007 and 2009. The model domain should thus be regarded as representing an  
19 approximation to conditions in recent years rather than a specific snapshot in time. Surface  
20 velocities following the inversion were in agreement with observed velocities over the  
21 grounded region (approximately  $150 \text{ m a}^{-1}$  or less). Subglacial friction coefficients for grounded  
22 portions of the domain were determined assuming a linear bed friction law and friction  
23 coefficients were converted to SI units and rescaled ( $\times 10^{-5}$ ) for use in HiDEM. Rescaling bed  
24 friction coefficients is necessary to produce useful ice-displacement magnitudes, because  
25 HiDEM simulates glacier sliding and fracture taking place over timescales of seconds, whereas  
26 in reality these processes take place over timescales of hours to years (van Dongen et al., 2020).

27  
28 Experiments with HiDEM were designed to test two hypotheses on the causes of the observed  
29 fragmentation of TEIS: 1) fragmentation is related to a reduction of backstress on the shelf,  
30 consequent upon progressive unpinning; and 2) fragmentation is related to progressive  
31 weakening of the ice and continuing backstress from the pinning point. To test these  
32 hypotheses, we conducted a matrix of runs with different combinations of ice damage density  
33 and pinning point friction. The latter is used to represent the degree to which the TEIS was  
34 pinned. Simulations that utilised the rescaled bed friction coefficient noted above, hereafter  
35 referred to as *baseline friction*, represented a less-pinned TEIS. A fully-pinned TEIS was  
36 represented by placing “no-slip” constraints on particles that were in contact with the pinned  
37 region. It is appropriate to apply this no-slip boundary condition given that HiDEM is used to  
38 simulate the elastic component of the TEIS deformation. Other, slower processes of ice motion  
39 would not result in substantial movement over the short-duration time scales of motion  
40 considered in HiDEM simulations.

41  
42 Ice damage density is represented by the proportion of initially broken bonds in a HiDEM  
43 simulation. In the present study, ice strength was varied by adjusting initial ice damage density  
44  $d$  from 0 (no damage) to 0.3 (moderate damage) to 0.6 (highly damaged). This damage index  
45 represents a reduction in load-bearing area and thus has a similar physical meaning to damage  
46 as commonly defined (e.g. LeMaitre, 2012; Borstad et al. 2012). However, the dependence of  
47 modelled ice properties on particle and bond parameters means that values of  $d$  are not  
48 directly comparable to damage variables used in other studies, including the BISICLES model

1 discussed below. Ice damage typically increases during model runs as beams are broken in  
 2 response to inter-particle stresses. Unlike the initial prescribed damage  $d$ , which is  
 3 macroscopically uniform and isotropic, emergent damage is localised and anisotropic, typically  
 4 taking the form of fractures and shear zones and therefore a more realistic simulation of  
 5 damaged ice (Åström and Benn, 2019).

6  
 7 The HiDEM settings and experiments are summarized in Table 1. In the form used in this study,  
 8 HiDEM is a purely brittle-elastic model and does not include viscous deformation. For  
 9 simulations of short-lived calving processes it is sufficient to allow the domain to evolve under  
 10 the gravitational and buoyant forces arising from ice geometry and water depth. Crevasses and  
 11 rifts on ice shelves, however, typically propagate on long timescales during which ice can  
 12 undergo large displacements, and for such cases some external model forcing is often desirable  
 13 (e.g. Åström and Benn, 2019; Åström et al., 2021). In the runs reported here, we applied a force  
 14 at the upstream boundary of the domain that produced a close approximation of the observed  
 15 velocity structure near the grounding line. The simulated TEIS domain contained  $10^9$  particles  
 16 and was run over 36 hours using 2048 cores on the Mahti supercomputer at the CSC-IT Centre  
 17 for Science.

18  
 19 **Table 1: Key parameters in simulations using the Helsinki Discrete Element Model (HiDEM)**

20

Model	Parameter	Value
HiDEM	Beam width:particle diameter	0.6
	Tensile breaking strain	0.0005
	maximum bending angle (radians)	0.03
	Young's modulus (Pa)	1.0e-9
	Damage ( $d'$ ; proportion of initially broken bonds)	0.1; 0.3; 0.6
	Friction scale	1.0e-5 (baseline friction); 1e-4 + no-slip constraints over the pinning point ("no-slip")
	Particle size (m)	40
	Timestep (s)	0.001
	Duration of simulation (s)	1200

21  
 22 BISICLES is a continuum ice flow model based on a vertically integrated stress balance equation  
 23 (Cornford et al 2020). Its treatment of fracture processes is limited to the calculation of a scalar  
 24 damage  $D(x, y, t)$ , which modifies the effective viscosity. BISICLES includes a model of damage  
 25 evolution that attempts to evolve damage according to a simple relationship with local stress  
 26 and damage advected from upstream (Sun et al., 2016). That model, however, proves too  
 27 simplistic to model TEIS and TWIT accurately. Instead, we estimate  $D(x, y, t)$ , together with  
 28 basal friction  $\tau_b(x, y)$ , through regularized optimizations conducted for monthly intervals  
 29 through 2016 to 2020, using our velocity data derived from Sentinel-1 imagery. The model  
 30 domain covers the Amundsen Sea Embayment drainage basins including the entire Thwaites  
 31 Glacier, and is based upon the BedMachine v.2 ice thickness and bedrock elevation (Morlighem,  
 32 2020). As in the HiDEM simulations, the pinning point at the northern tip of TEIS comprises two  
 33 separate pinning regions. In contrast to HiDEM, the vertically integrated stress model within  
 34 BISICLES does not depend on thickness above flotation in the pinning point, but only on its  
 35 extent.

1 To assess the possible dynamic response of Thwaites Glacier to further changes on TEIS, we  
 2 conducted a set of simulations to 2116 with varying damage, ice shelf thickness  $h(x, y, t)$  and  
 3 pinning point friction. All simulations start with the basal friction  $\tau_b$  calibrated to March 2016,  
 4 which then evolves according to a regularized Coulomb law (Joughin et al., 2019, Zoet and  
 5 Iverson, 2020),

$$6 \quad |\tau_b| = \frac{\beta^2 |\mathbf{u}|^{\frac{1}{3}}}{(|\mathbf{u}| + u_0)^{\frac{1}{3}}} \quad (1)$$

7  
 8 where  $\beta^2(x, y)$  is a basal friction coefficient,  $\mathbf{u}$  is the horizontal ice velocity, and  $u_0$  is a  
 9 regularization parameter. A simple set of calving criteria are also in play: ice is removed  
 10 wherever  $(1-D)h < 5$  m or where ice speed exceeds  $10^4$  m a<sup>-1</sup>. The damage calving criterion is  
 11 similar to the full-depth crevasse calving law of Nick et al. (2010), and determines the position  
 12 of the ice front rather than a calving rate. Fourteen experiments are reported here and  
 13 summarized in Table 2, designed to assess the impact of different physical processes. Each  
 14 experiment is named according to the evolution of the ice shelf damage  $D(x, y)$  and the choice  
 15 of ice shelf melt rate and the choice of the basal friction regularization parameter in (1), with a  
 16 three letter code (e.g EMC, meaning ‘Extrapolation of damage, ice shelf Melting, and Coulomb-  
 17 like friction’)

18  
 19 Damage evolution follows one of three possibilities. Control experiments have  $D(x, y)$  set to the  
 20 optimal values determined for March 2016. Extrapolation experiments have  $D(x, y)$  increase  
 21 linearly in time within the ice shelf from 2016 in order to reach the optimal values for March  
 22 2020, and then continue to increase linearly to 2026 at which point  $D(x, y) \sim 1$  across the shear  
 23 zone between the pinning point and the remainder of TEIS, and across the shear margin  
 24 between TEIS and TWIT. Unpinning experiments set the ice thickness to zero in a narrow region  
 25 surrounding the pinning point from 2016 onward, creating a new northern calving front.

26  
 27 Ice shelf melt rates also follow one of three different schemes. Control experiments fix the ice  
 28 shelf thickness in time. Retreat experiments allow the ice shelf to evolve dynamically and fix the  
 29 melt rate to zero, but prevent present day floating ice regions from grounding, so that the  
 30 grounding line may retreat but not advance. Melting experiments apply one of the melt rate  
 31 formulae described in Hongju et al 2018, leading to melt rates:

$$32 \quad M = \left\{ \begin{array}{ll} 0 & rh < 150 \\ \frac{160 r(h - 150)}{850} & 150 \leq h < 1000 \\ \frac{160}{160} & 1000 < h \end{array} \right\} \text{ma}^{-1} \quad (2)$$

34  
 35  
 36 The basal friction regularization parameter was set to either  
 37  $u_0 = 50$  (ma<sup>-1</sup>), resulting in plastic bed (Coulomb-like) friction across much of TG, or to  $u_0 =$   
 38  $300$  (ma<sup>-1</sup>), where hard bed (Weertman-like) sliding dominates.

39  
 40

1 **Table 2: BISICLES experiments**

2

Experiment	$u_0$ (ma <sup>-1</sup> )	Damage Evolution	Melt rate evolution
00C	50	<b>Control:</b> $D(x,y)$ fixed at the values determined for March 2016	<b>Control:</b> Ice self thickness remains constant
00W	300		
0MW	50		<b>Melting:</b> melt rate up to 160 (ma <sup>-1</sup> )
0MV	300		
EOW	50	<b>Extrapolation:</b> $D(x,y)$ increases linearly within the ice shelf from 2016 to reach the value determined for March 2020, and then continues to increase at the same rate until 2026.	<b>Control</b>
EOC	300		<b>Retreating:</b> melt rate calculated to prevent ice shelf grounding.
ERW	50		
ERC	300		<b>Melting</b>
EMW	50		
EMC	300		
URW	50	<b>Unpinning:</b> ice thickness in the shear margin between the TEIS and TWIT set to zero in 2016.	<b>Retreating</b>
URC	300		<b>Melting</b>
UMW	50		
UMC	300

The large-scale velocity structure of TEIS underwent little change over the period 2015 to 2020 (Fig. 2). On all velocity maps, ice flow vectors on to the shelf are aligned approximately normal to the general trend of the grounding line, and over most of the shelf ice progressively veer towards the northeast as ice approaches the pinning point. The only exception to this pattern is in a relatively small region west and south-west of the pinning point, where ice flow is predominantly towards the north-west. Over most of the shelf, flow speeds are typically in the range 1 to 3 m/day and an order of magnitude lower at and around the pinning point. Sustained shrinkage of the area bounded by the 0.2 m/day velocity contour indicates progressive loss of traction over the pinning point, consistent with previous work that demonstrated ongoing ice thinning in this region (Fig. 2; Alley et al., 2021; Wild et al. 2021).

**3.2 Fracture and strain 2015 - 2021**

Although the large-scale velocity structure of TEIS has remained relatively constant from 2015 to 2020, considerable changes in fracture patterns and strain rates occurred during this period.

In Sentinel-1 imagery, evidence for fracturing takes two forms: 1) broad surface troughs indicating depressions above basal crevasses, and 2) sharp-edged linear features indicating surface crevasses or full-depth rifts (e.g. Luckman et al., 2012). In the earliest Sentinel-1 images (2014), sets of sub-parallel basal crevasses occur down-flow of the grounding line and upstream of the pinning point (Fig. 3). The latter set extends diagonally across the shelf from southwest to northeast, coincident with the transition between rapidly and slowly moving ice shown in Figure 2. This region is interpreted as a narrow shear zone (S: Fig. 3) between slowly-moving ice over the pinning point (P) and more rapidly-flowing ice on the main part of the shelf, hereafter termed the *TEIS shear zone*. In late 2016 and early 2017, a set of secondary basal crevasses started to develop at a high angle to the TEIS shear zone, on the upstream (southern) side (T: Fig. 3). These subsequently propagated southward across the shelf and increased in number.

1 During 2017, the easternmost of these secondary crevasses developed into a full-depth rift,  
2 visible as a sharp-edged feature on the Sentinel imagery and leading to the detachment of a  
3 tabular berg ~18 km long and up to 2 km wide (C1, Fig. 3). Other areas of active calving are  
4 evident on both the eastern (C2) and western (C3) flanks of TEIS, the latter releasing tabular  
5 bergs into the area formerly occupied by the shear margin between TEIS and TWIT. Evidence  
6 for full-depth rifting within the TEIS shear zone was initially confined to short wing cracks across  
7 blocks bounded by basal crevasses, but became increasingly widespread through time.

8  
9 Rapid evolution of the shear zone since 2018 is further illustrated by velocity gradients and  
10 patterns of shear strain (Figs. 4 and 5). In 2018, a narrow band of high strain existed in the  
11 northeastern portion of the shear zone, while strain in the remainder of the shear zone was  
12 lower in magnitude and distributed over a much wider area. In late 2020, a second narrow  
13 shear band appeared at the southwest end of the shear zone, then both bands connected and  
14 extended across the full extent of the shelf by early 2021, indicating a transition to full-  
15 thickness fracture. Velocity gradients across the southwestern half of the shear zone (Fig. 5)  
16 show distributed strain in the first quarter of 2020, suggesting predominantly viscous  
17 deformation or strain distributed across numerous fractures. During 2020 all velocity profiles  
18 show increasing localization of strain as the shear zone transitioned to full-depth fracture.  
19 Increasing shear localization is accompanied by an increase in ice velocity on the upstream side  
20 of the shear zone and a decrease on the down-flow (pinning point) side. On the upstream side,  
21 ice acceleration is substantial and ongoing (Fig. 6), with >40% increase in ice speed in the  
22 central part of TEIS between 2018 and 2021.

### 23 **3.3 Long-term perspective: Velocity and strain from MODIS data 2002 - 2021**

24 The shear zone on TEIS was already a well-established feature in 2014, when the Sentinel-1  
25 data begins. Evolution of TEIS prior to 2014, and the possible origin of the shear zone, can be  
26 inferred using MODIS and other historical data (Alley et al., 2021). These data are at a lower  
27 spatial resolution (500 m) than the Sentinel-1 imagery, and strain rates were calculated over a  
28 longer length scale (2500 m). This precludes detailed analysis, but the MODIS data provide a  
29 valuable record of large-scale patterns of velocity and strain and their changes through time.

30  
31 Figure 6 shows a time series of velocity in the central part of TEIS, c. 15 km upstream of the  
32 pinning point (magenta circle on Fig. 4). The ice accelerated between 2002 and 2006, then  
33 rapidly decreased to a minimum in 2009 before gradually increasing until 2020 when the  
34 current acceleration began. The 2002-2006 acceleration is attributed to strong coupling  
35 between TEIS and TWIT (Alley et al., 2021). The TWIT increased in speed after 2002 (Miles et  
36 al., 2020), possibly in response to progressive unpinning (Tinto and Bell, 2011), and the strong  
37 shear margin between the two portions of the shelf allowed TEIS to be dragged forward (Alley  
38 et al., 2021). After 2006, the shear margin between TEIS and TWIT fragmented and weakened,  
39 reducing coupling and allowing TEIS to decelerate. Meanwhile, TWIT fragmented and  
40 transitioned into a 'mélange ice shelf' and continued to accelerate (Miles et al., 2020; Alley et  
41 al., 2021).

42  
43 Patterns of strain on TEIS for three key time periods are shown in Figure 7. During the TEIS  
44 acceleration event (2005 - 2006), a band of positive (dextral; blue) shear strain outlines the  
45 shear margin between TEIS and TWIT, while a zone of negative (sinistral; red) shear is evident  
46 around the locus of the modern TEIS shear zone. Very high compressive longitudinal strain  
47 rates upstream of the TEIS pinning point indicate significant backstress during the acceleration  
48 event. After the acceleration event, the shear margin between TEIS and TWIT weakened,  
49

1 reducing the coupling between the TEIS and TWIT, and allowing TEIS to slow down again. This  
2 appears in the middle column of Fig. 7, where high shear strain rates delimit the weakened  
3 shear margin between TEIS and TWIT. In contrast, both shear strain and longitudinal strain  
4 rates are very low upstream of the TEIS pinning point. However, the first large fractures within  
5 the TEIS shear zone are visible in the MODIS imagery (marked with an arrow). Data for 2019-  
6 2020 show a renewed increase of shear strain in the vicinity of the shear zone and the  
7 development of extensive rifting. This phase of shear zone evolution has been discussed in  
8 detail above (Figs. 4 & 5).

9  
10 In summary, TEIS has undergone a process of fragmentation in the last five years, including  
11 brittle failure along a major shear zone up-glacier of the pinning point, formation of  
12 longitudinal tensile cracks on the main body of the shelf, and release of tabular bergs on both  
13 eastern and western flanks of TEIS. This pattern of failure is consistent with longitudinal  
14 compression and transverse extension of the shelf. The origins of the shear zone can be traced  
15 at least to the 2002 - 2006 acceleration event on TEIS, when zones of high longitudinal and shear  
16 strain developed upstream of the pinning point, indicating high backstress at that time.  
17 Fragmentation of the shelf increased since 2014, with increasing shear localization and  
18 extensive full-thickness rifting since late 2020. Weakening of the shear zone has been  
19 accompanied by rapid and ongoing acceleration of the ice on the upstream side.

## 20 21 **4. Modelling results**

### 22 23 **4.1 Fracture modelling with HiDEM**

24 The results of our HiDEM simulations show that widespread fracturing of the shelf does not  
25 occur in runs with low damage density ( $d < 0.3$ ) but does occur for runs with high damage  
26 density ( $d = 0.6$ ). Results from two runs with  $d = 0.6$  and different pinning point friction are  
27 presented here.

28  
29 Results for  $d = 0.6$  and baseline friction are shown in Figure 8A. The pinning point does not  
30 exert any significant influence on the pattern of ice displacement, and ice is able to slide over  
31 the proximal side of the submarine ridge then calves at its crest. Extensive rifting and calving  
32 occurs on the eastern flank of TEIS (highlighted by discontinuities in displacement magnitudes),  
33 but only limited fracturing occurs on the western flank.

34  
35 Figure 8B shows results for  $d = 0.6$  and a no slip boundary condition over the pinning point. In  
36 this case, a teardrop-shaped area of stagnant, largely intact ice extends upstream from the  
37 pinning point. Patterns of ice displacement on TEIS show progressive veering towards the  
38 northeast as it approaches the stagnant zone. Mobile and stagnant ice are separated by a shear  
39 zone, indicated by the sharp discontinuity in displacement magnitudes. The east and west  
40 flanks of TEIS exhibit widespread propagation of subparallel rifts and calving of tabular icebergs  
41 and tensile fractures are developed in the central part of the shelf (Fig. 8d).

42  
43 The fracture pattern in the 'no slip' simulation exhibits many similarities with that observed in  
44 February 2021 (Figs. 8C & 8D). Key common features are: 1) a triangular zone of slowly moving  
45 or stagnant ice extending upstream from the pinning point; 2) deflection of ice flow around the  
46 stagnant zone; 3) development of a shear zone (TEIS shear zone) upstream of the pinning point;  
47 4) and rifting and calving along the eastern and western flanks of TEIS. Tensile cracks appear on  
48 the mid-shelf in the HiDEM simulation, but unlike the separate linear fractures observed on  
49 TEIS they are part of stepped fractures with both shear and tensile components. This difference

1 probably reflects the lack of viscous processes in the model. The otherwise close similarity  
2 between the observed pattern of fracture and the 'no slip' HiDEM simulation support the  
3 conclusion that the recent fragmentation of TEIS occurred in response to uniaxial compression  
4 (i.e. opposing driving stress and backstress from the pinning point) and absence of transverse  
5 confining pressure.

#### 7 **4.2 BISICLES model results: damage evolution and future dynamics**

8 The observed increase in speed in TEIS between 2016 and 2020 can be reproduced in the  
9 optimized BISICLES model by reduced friction close to the 2016 TWIT grounding line and by  
10 increased damage in the shear zone region south-east of the TEIS pinning point and in the shear  
11 margin between TEIS and TWIT. The optimized damage and basal friction field computed for  
12 March 2016 to 2020 are shown in Figure 9 together with the associated observed and model  
13 speeds. Model speeds match observed speeds across the majority of Thwaites Glacier: the  
14 notable exception is TWIT, where brittle fracture and the formation of a mélange shelf are  
15 poorly described by the continuum model. There the mismatch is as much as  $500 \text{ m a}^{-1}$ , or 10%  
16 of the observed speed. Figure 10 shows the difference in basal traction, and the difference in  
17 damage, between March 2016 and March 2020, together with the difference in both observed  
18 and model velocities. The greatest relative changes in the basal friction are concentrated close  
19 to the TWIT grounding line and on the TEIS pinning point, perhaps due to grounding line  
20 retreat, or at least reduction in effective pressure. Damage around the TEIS pinning point  
21 increases from around 0.4 to around 0.8, while TEIS and TWIT are essentially separated from  
22 one another.

23  
24 We used the optimized basal traction and damage values as the starting point for forward  
25 model simulations (Fig. 11, Fig. 12, Appendix). In all cases, quite large changes occur to the  
26 velocity pattern on TEIS. The control experiments (00W,00C) exhibit a reduction in speed of  
27  $\sim 200 \text{ m/a}$  across both ice shelf regions and immediately upstream by 2032, caused by the  
28 thinning of the ice upstream and the resulting reduced gravitational driving stress. Damage  
29 extrapolation and unpinning experiments without sustained future melting (E0W, E0C, ERW,  
30 ERC, URW, URC) see an increase in speed on TEIS upstream from the pinning point, attributed  
31 to reduced ability of the shelf to support backstress. In contrast, ice around the grounding line  
32 of TWIT and the eastern grounding line of TEIS decreases in speed, for similar reasons to that in  
33 the control experiments. Experiments ERW and ERC (extrapolated damage, dynamically  
34 evolving ice shelf thickness) result in faster flow over most of TEIS than either E0W or E0C  
35 (extrapolated damage, constant ice shelf thickness), with the ice shelf acceleration leading to  
36 thinning and a further loss of buttressing. The greatest speed increase is seen in experiments  
37 URW and URC, because a new calving front is created and hence additional tensile stress is  
38 imposed on the now unconfined shelf. In all cases, there is at most a modest increase in the ice  
39 flux across grounding line onto TEIS, even when large acceleration occurs on the shelf. On the  
40 other hand, experiments with sustained future melt forcing (OMW, OMC, EMW, EMC, UMW,  
41 UMC) see ice flowing faster across the whole region, more so when the TEIS damage is greater  
42 (EMW, EMC, UMW, UMC). These experiments also see grounding line retreat  $\sim 1 \text{ km/a}$  in both  
43 the TEIS and TWIT areas. The much greater retreat in these cases indicates a substantial loss of  
44 buttressing when the ice shelf thins close to the grounding line.

45  
46 The future contribution of Thwaites Glacier to sea level rise computed by the BISICLES model  
47 depends only weakly on changes around the TEIS pinning point. Figure 12 shows the discharge  
48 of ice above flotation, that is:

$$F_f(t) = \int_{\Omega_G} \nabla_H \cdot (\mathbf{u} (h - h_f)) d\Omega_G, \quad (3)$$

and the change in volume above flotation (VAF),

$$\Delta V_f(t) = \int_{\Omega_G} (h_f(t) - h_f(t = 2016)) d\Omega_G. \quad (4)$$

$\mathbf{u}$  is the horizontal ice velocity,  $h$  is ice thickness,  $h_f$  is the flotation thickness,  $\nabla_H$  is the horizontal gradient operator, and  $\Omega_G$  is the grounded part of the Thwaites drainage basin. The most important cause of variation between simulations is the sustained melt rate. Simulations that apply the melt rate of Eqn. (2) exhibit discharge of ice above flotation in excess of 180 Gt/a for the entire century long simulations, resulting in around 25 mm eustatic sea level rise by 2100, consistent with the comparable simulations of Hongju et al. (2018). Simulations without sustained ice shelf melt show a long-term trend with discharge declining from 180 Gt/a to 100 Gt/a and less than 10 mm eustatic sea level rise. The second most important cause of variations is the choice of friction law. Coulomb-like (plastic) models friction produce more discharge than Weertman-like simulations given sustained melt rates, where the grounded ice is generally accelerating, and less discharge otherwise. The effects of damage extrapolation and TEIS unpinning are visible as minor additional discharge early in each simulation, most prominently in the difference between experiments UMC and OMC to 2040. TEIS unpinning and the consequent ice shelf acceleration (experiments ERW, ERC, URW, URC) results in some additional grounding line retreat compared to the control experiments (00W, 00C) by the end of the 21<sup>st</sup> century (Figs. A1-A3).

## 5. Discussion

### 5.1 Observed and modelled fracturing

Sentinel-1 data, available since 2014, show that TEIS has transitioned from a largely intact ice shelf into an extensively fractured state, with full-depth fracturing along the TEIS shear zone, rifting and tabular calving along both eastern and western flanks, tensile fracturing in the central part of the shelf, and acceleration of ice flow. Concurrently, ice has been progressively decoupling from the submarine pinning point at its distal end.

The HiDEM modelling highlights the key role of backstress from the pinning point in this pattern of fracturing. The TEIS shear zone does not develop in runs where friction over the pinning point has the baseline values derived by rescaling output from the Elmer/Ice inversion. In contrast, a shear zone and other features similar to the observed fracture pattern are seen to develop in runs where a no-slip boundary condition is imposed over the pinning point. It may appear paradoxical that the shear zone fails to develop under model boundary conditions derived from observed ice geometry and dynamics. Two reasons may be suggested for this.

First, the inversion-derived friction coefficients over the pinning point may be unrepresentative because of uncertainties associated with the sea-floor topography, the inversion process in Elmer/Ice, and the subsequent rescaling for HiDEM. Radar data show the bedrock topography is up to 200 m shallower than indicated by the gravity inversion used as the basis for the model bed (Wild et al., 2021). Therefore some small local differences between our bed and the seafloor topography shown by Wild et al. (2021) may exist, however, the height above flotation is reasonable when considering the full pinning point region in our HiDEM domain. In the

1 Elmer/Ice inversion, the relatively small area of the pinning point may mean that the inverted  
2 basal resistance is too low as the result of spatial smoothing in the regularization process.  
3 Rescaling of friction to account for the different functional timescales of HiDEM and Elmer/Ice  
4 introduces further uncertainties, particularly because HiDEM does not incorporate viscous  
5 processes. Taken together, these factors could mean that the bed is 'too slippery' over the  
6 pinning point in the HiDEM simulations using the baseline friction values.

7  
8 Second, the necessity for high pinning point friction to create a shear zone in HiDEM may mean  
9 that the observed TEIS shear zone was initiated at a time when pinning point friction was  
10 greater than it was when the model input data were acquired (2007 and 2009 for MEaSURES  
11 and 2013-2014 for REMA). It is therefore possible that the TEIS shear zone developed when the  
12 pinning point provided greater backstress, and that progressive weakening through shear  
13 localisation and damage evolution has allowed the shear zone to persist although pinning point  
14 friction has been diminishing. Whatever the case, the HiDEM results are unequivocal: the  
15 observed fracture pattern requires backstress from the pinning point sufficient to initiate and  
16 sustain shear failure in the shelf. That is, backstress must consistently exceed the evolving  
17 effective strength of TEIS.

18  
19 In the HiDEM runs, a high initial damage density ( $d = 0.6$ ) is required to produce a shear zone.  
20 This does not imply that a similar degree of pervasive damage was required to initiate the TEIS  
21 shear zone. As noted above, the properties of ice in HiDEM reflect a range of parameters and  
22 we chose damage density as a transparent and easily tunable control on ice strength. It must  
23 also be emphasised that the version of HiDEM used here is purely brittle-elastic, and does not  
24 incorporate viscous deformation. This means that the model cannot include processes likely to  
25 have been important on TEIS, particularly viscous shear localisation in the early development of  
26 the shear zone. In addition, evolution of TEIS likely involved a number of factors not included in  
27 the simulations, such as basal roughness elements including advected crevasses and basal  
28 channels.

## 29 30 **5.2 Causes of fragmentation of TEIS**

31 The transformation of TEIS from a largely intact ice shelf into its currently fragmented state  
32 suggests the pinning point has shifted from being a stabilising to a destabilising influence.  
33 Formerly, backstress from the pinning point was sufficient to constrain ice flow, but insufficient  
34 to initiate fracturing. At some point the balance shifted, such that backstress from the pinning  
35 point exceeded the effective strength of the ice, and damage was able to accumulate. This shift  
36 may have occurred for three fundamental reasons:

- 37  
38 1. Changes in resistive stresses at the grounded margins of the shelf;
- 39  
40 2. Changes in stress patterns due to interactions between TEIS and TWIT; and
- 41  
42 3. Changes to the effective strength of the shelf.

43  
44 The grounded margins of TEIS have undergone overall retreat in recent decades. The area of  
45 ice-bed contact at the TEIS pinning point has reduced (Wild et al., 2021; Fig. 2), and the  
46 grounding line at the upstream boundary of TEIS has retreated (e.g. Rignot et al., 2014; Milillo  
47 et al., 2019). In addition, interferograms of TEIS for the 1990s indicate the presence of a  
48 possible additional pinning point in the middle of TEIS (Rignot, 2001), which is not evident in  
49 more recent times. While reduction in the area of the TEIS pinning point may be expected to

1 have reduced backstress on the shelf, the other changes may have increased longitudinal  
2 compressive stresses on the floating ice.

3  
4 Concomitant with the changes to grounded margins, there have been large changes in the  
5 relationship between TEIS and TWIT. First, acceleration of TWIT after 2002 (itself likely a  
6 response to weakening of a sub-shelf pinning point) was transmitted across shear margin to  
7 TEIS, causing the observed speed-up between 2002 and 2006 (Fig. 6). This speed-up was  
8 associated with increased longitudinal and shear strain on TEIS, indicating increased loading on  
9 the shelf. Subsequently, fragmentation and opening of the shear margin exposed the western  
10 flank of TEIS, reducing lateral confining stress on that side.

11  
12 Several factors may have contributed to weakening TEIS in recent decades. Basal melting in  
13 response to incursions of warm, deep water has reduced ice-shelf thickness, with basal melt  
14 rates typically on the order of 5 m/yr (Seroussi et al. 2017; Wåhlin et al., 2021; Alley et al.,  
15 2021). Focused basal melting in sub-shelf channels can increase basal roughness, create local  
16 stress concentrations and interact with fracture processes. Weakening may also occur through  
17 the advection of damage from upstream, and basal crevasses or other fractures could seed  
18 additional damage when they reach different stress regimes. Finally, damage can accumulate  
19 through time via positive feedbacks between damage and strain (Åström and Benn, 2019;  
20 Lhermite et al., 2020).

21  
22 The recent evolution of TEIS may have involved a combination of all the above factors. On the  
23 balance of available evidence, we propose the following sequence of events as the most likely  
24 cause of the recent fragmentation. The TEIS shear zone was initiated, or was significantly  
25 modified, in the mid-2000s, when TEIS accelerated in response to stresses transferred across  
26 the strong shear margin with TWIT which was strong at that time (Alley et al. 2021). During the  
27 acceleration event, high longitudinal and shear strain rates developed upstream on TEIS in  
28 response to elevated longitudinal compression supported by backstress from the pinning point.  
29 Large fractures within the TEIS shear zone first appear in satellite imagery after the acceleration  
30 event, suggesting that damage was initiated or increased in response to elevated stresses (Fig.  
31 7). Fragmentation, opening and significant weakening of the shear margin between TEIS and  
32 TWIT removed confining pressure from the western flank of TEIS, encouraging transverse  
33 extension in response to ongoing longitudinal compression. Concurrently, damage on the shelf  
34 continued to accumulate due to positive feedbacks between damage and strain. Sentinel-1  
35 data show increasing development of tensile fractures since 2017 in response to transverse  
36 extension (Fig. 3), and increasing concentration of strain and extensive rifting within the TEIS  
37 shear zone since 2020 (Fig. 5). Thus, although backstress from the pinning point has likely  
38 diminished through time (Wild et al., 2021), accumulation of damage on TEIS has ensured that  
39 the ice in the shear zone has remained the weakest link in the system. Fragmentation of TEIS  
40 was not a consequence of unpinning; on the contrary, fragmentation reflects stresses  
41 originating at the pinning point acting on progressively weakening ice.

### 42 43 **5.3 Future implications of TEIS loss**

44 The BISICLES model results indicate that loss of strength in the shear zone or unpinning of TEIS  
45 will likely have little impact on basin-wide discharge from Thwaites Glacier. There is currently  
46 no evidence that the imminent loss of TEIS will hasten marine ice sheet instability or the demise  
47 of Thwaites Glacier. However, future evolution of Thwaites may be significantly influenced by  
48 calving processes along unbuttressed grounding lines, and it is possible that calving and iceberg  
49 overturn may increase, perhaps substantially, if the ice shelves are lost.

1  
2 Water depths along the grounding line of TEIS are currently in the range 400 - 700 m, which is  
3 below the likely threshold for ice-cliff instability (cf. Bassis and Walker, 2012; Crawford et al.,  
4 2020). The glacier bed deepens substantially 40 km upstream of the current grounding line, but  
5 ice retreat to that point will involve calving by processes such as melt-undercutting,  
6 longitudinal extension and buoyant calving (e.g. Benn et al., 2007; Benn and Åström, 2019).  
7 Detailed observations and process modelling will be required to understand how ice shelf  
8 removal will affect calving processes and ice-retreat rates in this region (e.g. Winberry et al.,  
9 2020; Crawford et al., 2020).

## 10 11 **6. Conclusion**

12  
13 Backstress from the pinning point, once a crucial source of support for TEIS, is now hastening its  
14 destruction. Complete fragmentation of TEIS appears to be imminent and disintegration could  
15 occur sooner than the ~10 year timescale implied by rates of thinning and unpinning (cf. Wild et  
16 al., 2021). Complete loss of the shelf may follow, although the former pinning point and fast ice  
17 may retard the evacuation of icebergs in much the same way as currently observed on TWIT.

18  
19 The main implications of this work extend farther than the immediate future of Thwaites  
20 Glacier. Past observations of Antarctic ice shelf disintegration implicate two main mechanisms  
21 for ice shelf collapse: hydrofracture and unpinning. It is already clear that surface melting is  
22 neither a necessary nor sufficient condition for ice shelf disintegration, and our modelling  
23 results show that unpinning does not produce the observed fracture patterns on the TEIS.

24  
25 Our remote-sensing observations and modelling results suggest that a third mechanism, the  
26 concentration of backstress in damaged ice upstream of a pinning point, will ultimately be  
27 responsible for the destruction of the TEIS, and may operate on other Antarctic ice shelves in  
28 contact with pinning points. The mechanism for damage and development of the shear zone on  
29 the TEIS was a dynamic interaction with the neighboring TWIT. The TWIT, which accelerated  
30 and disintegrated in response to unpinning, caused the TEIS to accelerate and to develop the  
31 prominent shear zone where strain is continuing to concentrate. This shear zone may have  
32 been further weakened by direct basal melt (Wählin et al., 2021), but the continued strain  
33 concentration and rift formation implicate dynamics as the ultimate destabilising mechanism.

34  
35 On ice shelves in steady state, pinning points play a crucial role in their stability and in  
36 buttressing the upstream flow of ice off the Antarctic continent. If basal melt and/or dynamic  
37 interactions upset this balance, stresses are likely to concentrate upstream of pinning points,  
38 causing irreversible damage. In most circumstances, pinning points are essential for ice shelf  
39 stability, but as ice shelves thin and weaken, pinning points can provide the seeds of their  
40 demise.

7 pinning point, outlined in black, from the MEaSURES 2011 grounding line (Rignot et al. 2016).  
8 Background images are from Landsat-7 (left-hand column: January 13, 2005; middle column:  
9 December 13, 2010) and Landsat-8 (right-hand column: November 12, 2019). The first major  
10 crevasses within the location of the current shear zone became visible in Landsat imagery  
11 around 2010, and an example is indicated by the arrow in the middle column.

3 **Figure 8:** Modelled and observed fractures on the Thwaites Eastern Ice Shelf. Panels A and B  
4 show ice displacement patterns simulated in HiDEM. Panel C shows the satellite observations  
5 and labels key features as in Fig 3 (S - S: TEIS shear zone; T: tensile cracks; C1 - C3:  
6 calving along rifts; P: pinning point). Panel A illustrates that the observed shear zone does not develop in the  
7 simulation with the baseline friction boundary condition over the pinning point (i.e. values  
8 derived from the Elmer/Ice inversion rescaled for HiDEM) and damage density = 0.6. The zone  
9 of large displacements around TEIS (yellow) consists of mélange and calved icebergs. Panel B  
10 shows the sharp displacement gradient (shear zone) between the main body of the TEIS and  
11 the triangular area of stationary ice extending from the pinning point in the HiDEM simulation  
12 with a no-slip boundary condition over the pinning point and damage density = 0.6. Panel D  
13 illustrates fracture patterns resulting from the HiDEM simulation, depicting surface elevation in  
14 greyscale shading and bonds broken during the simulation in blue. Features with close  
15 correspondence to the observations are also indicated.

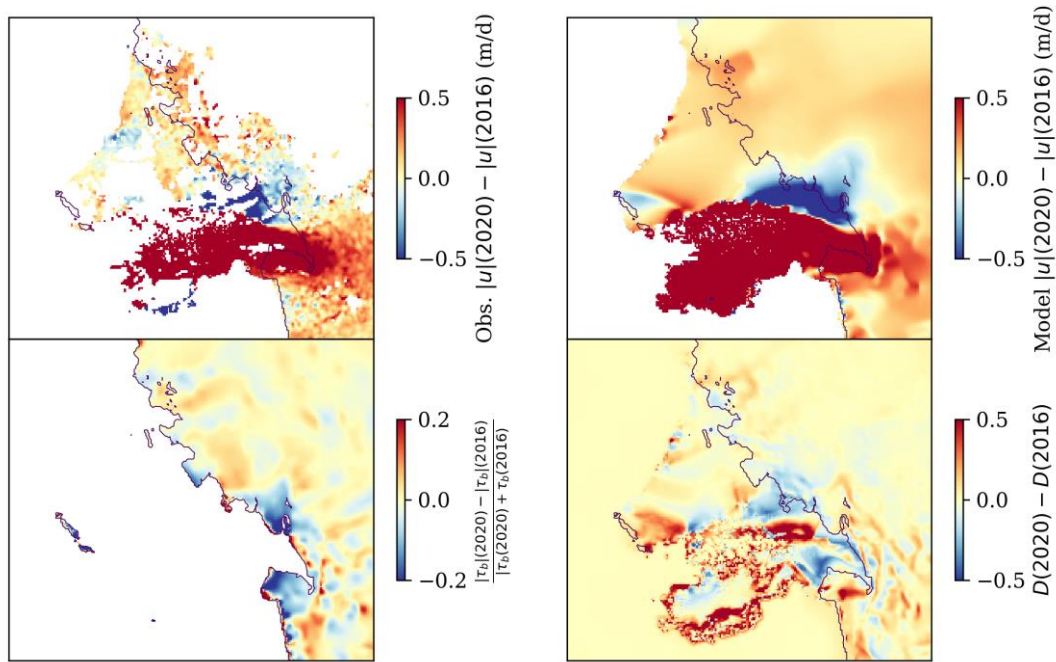

16  
17

 2 **Figure 9:** BISICLES inverse problem results: March 2016-2020. The first and second columns  
 3 show the optimized model velocities and observed velocities; the third column shows the misfit  
 4 between modelled and observed velocities; and the fourth and fifth columns show the resulting  
 5 optimized basal traction and damage. Each row shows data for March of one year.

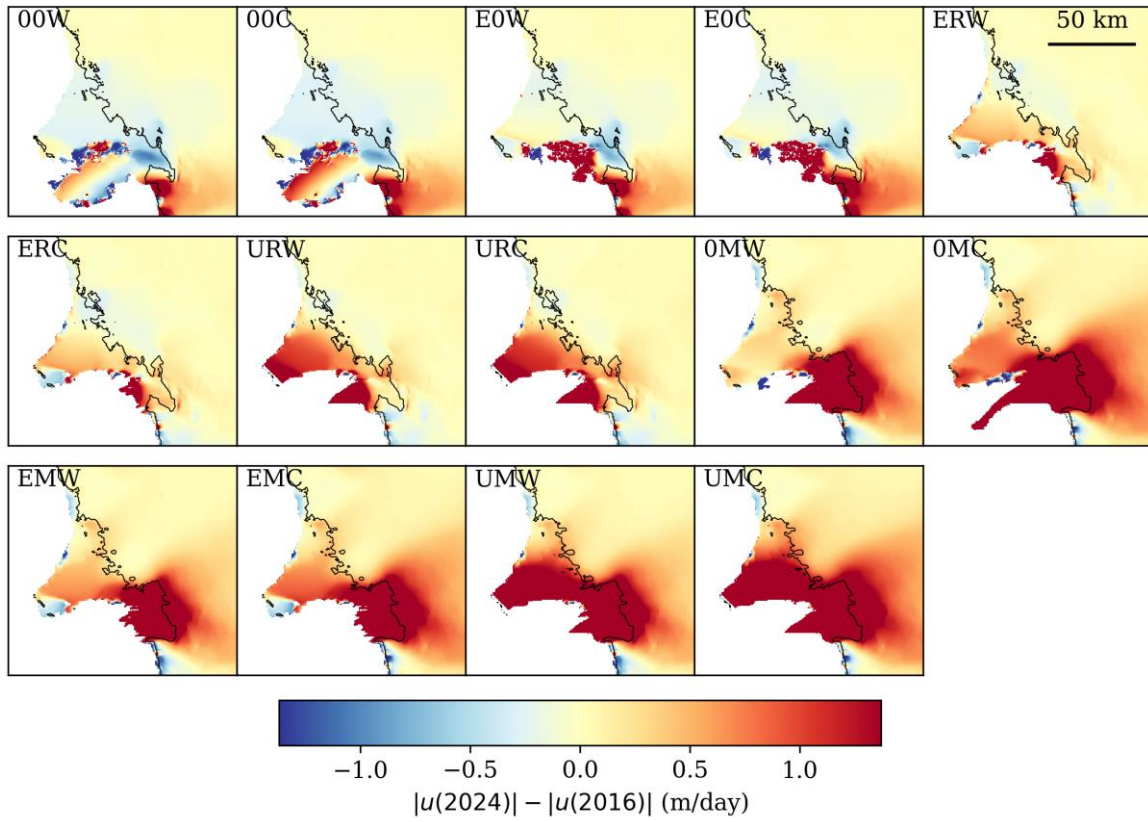

**Figure 11:** Output of BISICLES simulations of TEIS, showing differences in velocity between 2016 and 2032, and the 2032 grounding line (See appendix for equivalent panels with simulation end years of 2024, 2064 and 2112). Control experiments (00W,00C) see TEIS and the upstream ice slow down as the geometry relaxes. Damage extrapolation and unpinning experiments without sustained future melting (E0W,E0C,ERW,ERC,URW,URC) parts of TEIS speed up and a lower rate of upstream slow down. Experiments with sustained future melt forcing (OMW,OMC,EMW,EMC,UMW,UMC) see ice flowing faster across the whole region, more so when the TEIS damage is greater (EMW,EMC,UMW,UMC).

1  
 2 **Figure 12:** Discharge of ice above flotation  $F_f$  and change in volume above flotation (VAF),  $\Delta V_f$   
 3 associated with modelled changes to TEIS. Colours and line styles are grouped according to  
 4 melt forcing and friction parametersation. Dark (blue/grey/black) lines show the results of  
 5 simulations with sustained future melting, bright lines (red, orange, purple) show the result of  
 6 simulations without sustained future melting, Solid lines represent simulations with Coulomb-  
 7 like friction, dashed lines Weertman-like friction.
