Abstract. Monitoring the evolution of ice shelf damage such as crevasses and rifts is important for a better understanding of the mechanisms controlling the breakup of ice shelves and for improving predictions about iceberg calving and ice shelf disintegration. Nowadays, the previously existing observational gap has been reduced by the Copernicus Sentinel-1 Synthetic Aperture Radar (SAR) mission that provides a continuous coverage of the Antarctic margins with a 6 or 12-day repeat period. These unprecedented coverage and temporal sampling enable for the first time a year-round systematic monitoring of ice shelf fracturing and iceberg calving, as well as the detection of precursor signs of calving events. In this paper, a novel method based on SAR interferometry is presented for an automatic detection and delineation of active cracks on ice shelves. Active cracks cause phase discontinuities that are extracted automatically by applying a Canny edge detection procedure to the spatial phase gradient derived from a SAR interferogram. The potential of the proposed method is demonstrated in the case of Brunt Ice Shelf, Antarctica, using a stack of 6-day repeat-pass Sentinel-1 interferograms acquired between September 2020 and March 2021. The full life cycle of the North Rift is monitored, including the rift detection, its propagation at rates varying between 0.35 km d⁻¹ and 1.29 km d⁻¹, and the final calving event that gave birth to the iceberg A74 on 26 February 2021. The automatically delineated cracks agree well with the eventual location of the ice shelf edge after the iceberg broke off. The stress field variations observed in the interferograms are attributed to a rigid-body rotation of the ice about the expanding tip of the North Rift in response to the rifting activity. The extent of the North Rift is captured by SAR interferometry well before it becomes visible in SAR backscatter images, hence highlighting the high sensitivity of SAR interferometry to small variations in the ice shelf stress field and its potential for detecting early signs of natural calving events, as well as ice shelf fracturing and damage development in response to atmospheric and oceanic warming caused by climate change.

25 1 Introduction

Because of their buttressing effect that regulates the upstream flow of the grounded ice sheet, ice shelves play a key role in the mass balance of the Antarctic ice sheet. Ice shelf calving, especially for ice shelves that originate from large tributary glaciers, constitutes one of the main contributions to the mass loss in Antarctica (the IMBIE team, 2018; Rignot et al., 2019). However, predictions about this contribution remain uncertain due to the poor understanding of the mechanisms controlling

ice shelf break up and the difficulty to model them (Sun et al., 2017; Cook et al., 2018), partly due to a lack of comprehensive observational data. Ice shelves can be structurally weakened by processes such as ice shelf thinning, that leads to ice flow speedup and increased shearing, or such as ice shelf retreat that results into unpinning. These processes may trigger a feedback response, thereby enhancing damages such as deeply crevassed areas and open fractures, increasing the ice velocity gradient and further weakening the ice shelf structure (Lhermitte et al., 2020). The complex response of an ice shelf to rifting, the difficulty to predict ice shelf disintegration and the resulting uncertainties in mass balance models highlight the need for systematic monitoring of the damage evolution (Pattyn et al., 2017).

On-site measurements of ice shelves and active rifts from e.g. ground penetrating radar, time-lapse camera or GPS provide valuable insights for monitoring damages and better understanding the mechanisms leading to rift propagation (Banwell et al., 2017; King et al., 2018; De Rydt et al., 2019). However, field missions are expensive, necessitate heavy logistics and only focus on a specific area (usually close to a base station) for limited periods in time. Therefore, despite their unquestionable value, they provide no feasible solution for continuous long-term and large-scale monitoring of ice shelf rifting systems.

Nowadays, the majority of the Antarctic ice shelves is routinely monitored with optical and radar satellites, providing dense image time series that enable the continuous observation of fracture opening, propagation, widening and iceberg calving in near real-time. For damage monitoring, Synthetic Aperture Radar (SAR) sensors constitute a good alternative to optical satellite imaging thanks to their all-day/all-weather/year-round observing capability. Furthermore, SAR signal penetrates through dry snow that can fill and obscure cracks in optical images. In particular, the acquisition strategy of Sentinel-1 provides a continuous coverage of almost the entire ice sheet margin of Antarctica with 6- and 12-day repeat intervals, which enables the systematic surveillance of ice shelf fracturing with radar imaging for the first time (Torres et al., 2016).

Previous surveillance of cracks was performed through visual analyses and only few studies investigated automatic methods for mapping the fracturing of ice shelves. Moctezuma-Flores and Parmiggiani (2016) proposed the use of a morphological filter for reducing speckle noise in SAR backscatter data, followed by a stochastic segmentation for mapping the pre-collapse fractured area of Nansen Ice Shelf. However, this approach was applied on a subset of the SAR image focusing on a widely opened fracture. In practice, SAR backscatter images have a limited sensitivity to narrow cracks in the early stage of their development because of the sensor resolution and the variable contrast dependent on the viewing geometry. Edge detection performed on wide SAR images often misses thin cracks and may confuse fractures with other topographic features, e.g. calving fronts, if no contextual information is used.

In addition to SAR backscatter imaging, a few studies reported on the potential of SAR interferometry (InSAR) for mapping rifting activity (Rignot and MacAyeal, 1998; Larour et al., 2004; Hogg and Gudmundsson, 2017; De Rydt et al., 2018). These studies showed that, in an interferogram, opened fractures correspond to well-defined and visually identifiable phase discontinuities. Rignot and MacAyeal (1998) identified rifts as branch-cut discontinuities and interpreted the fringe patterns over downstream ice shelf fragments as due to a rigid-body rotation about an axis perpendicular to the ice shelf surface and located at the tip of the rift. The analysis of double difference interferograms and the modelling efforts presented in the

complementary paper by MacAyeal et al. (1998) support the hypothesis that this rigid-body rotation originates from gravitational ice flow. At the time of writing, to our knowledge, no study proposed a method for extracting the crack location automatically from the complex phase information supplied by an interferogram.

In this paper, we present an automatic method for delineating ice shelf fractures using Sentinel-1 Interferometric Wide (IW) SAR interferometry (Yague-Martinez et al., 2016). The proposed method exploits the changes in the ice stress field and the shearing of the ice flow caused by the rifting activity, which both translate into a discontinuous fringe pattern in an interferogram. We show that an active crack separates an ice shelf into distinct regions, characterized by fringe patterns with different orientations and different fringe rates that can be quantitatively derived by calculating the phase gradient, and that active cracks correspond to spatial phase discontinuities that can be mapped with an edge detection procedure. Because Brunt Ice Shelf (BIS) showed significant rifting activity in the past years (De Rydt et al., 2019), we select it as test site. The performance of the method is demonstrated using a set of 6-day repeat-pass Sentinel-1 interferograms acquired over BIS between September 2020 and March 2021. In particular, we track the activation and the propagation of a new rift, the North Rift, that led to the calving of iceberg A74 on 26 February 2021. Based on this study case, we demonstrate that SAR interferometry is sensitive to the dynamical response of an ice shelf to rifting activity and has potential to provide early indications of fracturing, not yet visible in SAR backscatter or optical satellite images.

In Section 2, the BIS test site is briefly described and, in Section 3, the ability of InSAR at capturing rifting activity is introduced. The delineation method and the processing line are described in Section 4, along with illustrating examples of intermediate processing steps. The capabilities and limitations of the method are also discussed. The Sentinel-1 dataset used for tracking the North Rift propagation on BIS and the processing parameters are detailed in Section 5. In Section 6, we analyze the results and present the evolution of the North Rift extent as captured by the InSAR-based delineation. Furthermore, we illustrate the gain of information provided by SAR interferometry versus SAR backscatter images and we attempt to identify the stress field variation using double difference interferograms. Finally, Section 7 summarizes the potential, the benefits and the limitations of the proposed method.

2 Test site

Brunt Ice Shelf is located along the Caird Coast in East Antarctica, in the eastern sector of the Weddell Sea (Figure 1(a)). It is connected to a larger ice shelf that is made up of the Stancomb–Wills Ice Tongue (SWIT) and the Riiser–Larsen Ice Shelf. The border with the SWIT is defined at the northeast of BIS by the Brunt–Stancomb Chasm (Anderson et al., 2014).

BIS presents a rich rifting system made of old and new fractures experiencing variable propagation rates, that are described in Thomas (1973) and more recently in De Rydt et al. (2018). The McDonald Ice Rumples (MIR), on the northeast part of the ice shelf tip, originate from the only pinning point constraining the ice flow, and play therefore a key role in the rifting system (Gudmundsson et al., 2017; De Rydt et al., 2019). On the southwest part of BIS, the Chasm 1 rift reactivated in November 2012 and progressively propagated towards the MIR to reach its current extent, after having been dormant for

three decades. In October 2016, a new rift named the “Halloween crack” appeared close to the MIR and expanded with a variable speed in the east direction (De Rydt et al., 2018). More resilient than first expected, to date neither Chasm 1 nor the Halloween crack have reached their rupture point yet, although Chasm 1 remains only connected by a short ice bridge of a few kilometers in length.

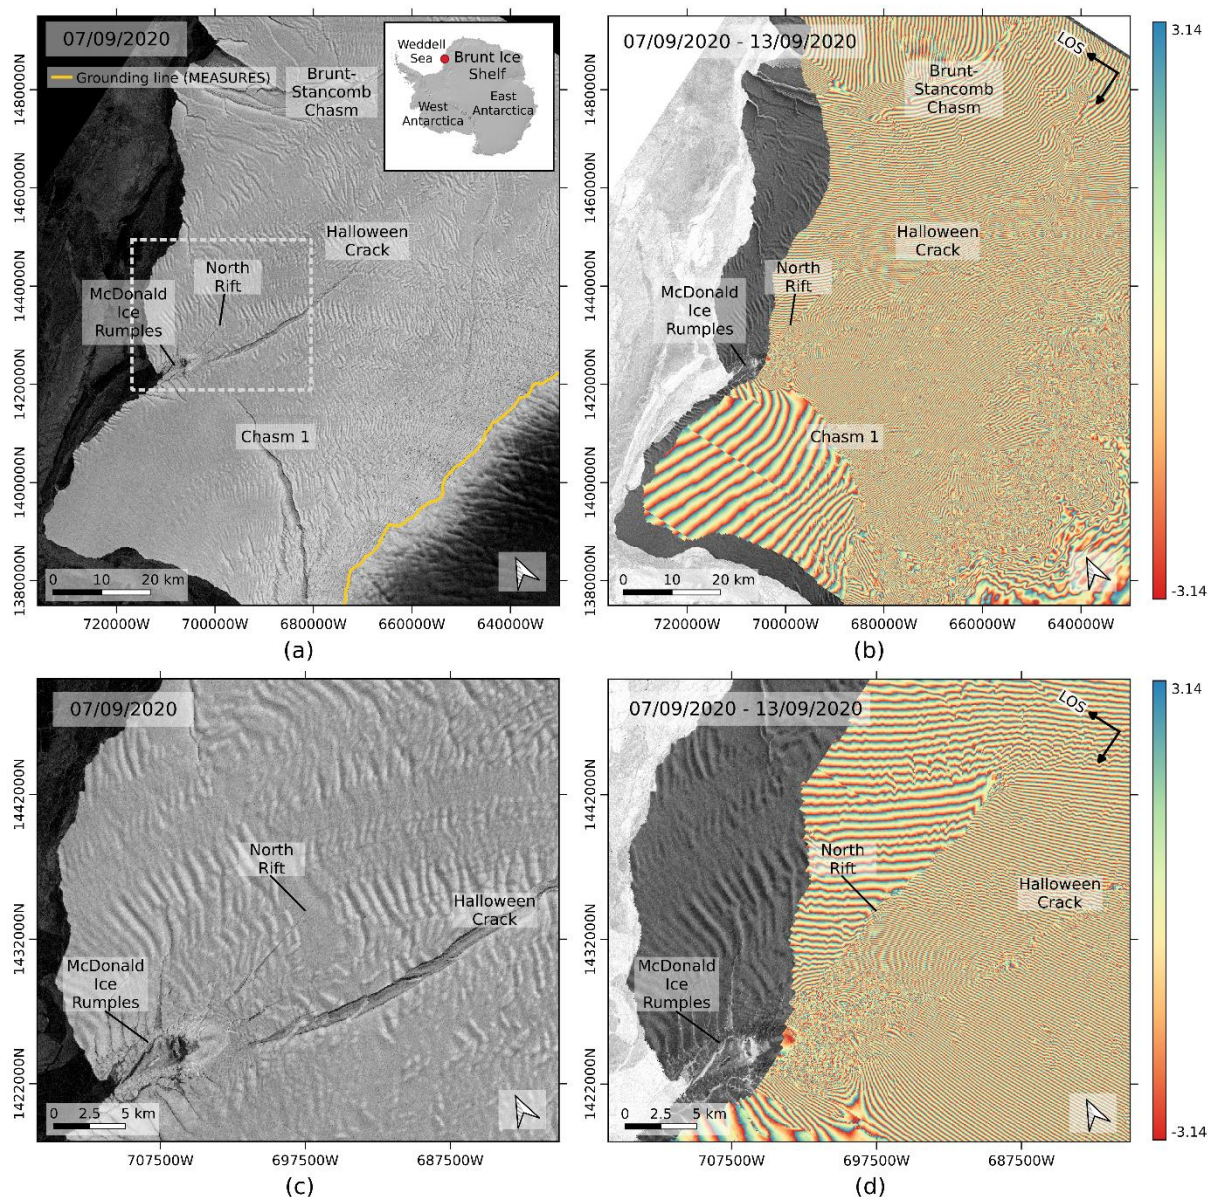

Figure 1: Rifting system on BIS. (a) Sentinel-1 brightness image acquired on 7 September 2020. The inset indicates the location of BIS over the REMA DEM (Howat et al., 2019) and the yellow line indicates the grounding line provided by the MEaSUREs dataset (Rignot et al., 2011, 2014 and 2016). **(b)** Sentinel-1 repeat-pass interferogram of 7–13 September 2020. **(c)** Close up of (a) whose extent is indicated by the gray frame. **(d)** Close up of (b).

105 In November 2021, a third rift - the North Rift - opened at the MIR and quickly spread towards the Brunt–Stancomb Chasm,
 leading to the calving of iceberg A74 (1270 km²) on 26 February 2021 (British Antarctic Survey, 2021). The formation of
 this iceberg constitutes the first major calving event on BIS since September 1971 (Thomas, 1973). In the following, we
 describe the InSAR-based method for delineating crack and illustrate it with an example on BIS. We then apply the method
 to a time series of repeat-pass interferograms and demonstrate its efficiency by tracking the activation and propagation of the
 110 North Rift.

3 Phase discontinuities across rifts

The efficiency of repeat-pass SAR interferometry for mapping ice motion and detecting ice surface deformation and stress
 (e.g. ice drift, grounding lines, grounding of pinning points, etc.) has long been established (e.g. Rignot et al., 1995, 2000,
 2011; Mouginot et al., 2019). SAR interferometry is able to capture displacements and deformations of an ice shelf as small
 115 as a fraction of the sensor wavelength, making it highly sensitive to changes in comparison with SAR backscatter imagery
 that can only provide information about cracks at the scale of the pixel resolution. Since 2014, the Sentinel-1 constellation
 offers interferometric capabilities at C-band with systematic acquisition, wide coverage, medium resolution and a reduced
 revisit cycle compared to former missions, therefore providing potential for a regular monitoring of ice shelf rifting activity
 with interferometry for the first time. The main acquisition mode of Sentinel-1 is the Interferometric Wide swath (IW) mode,
 120 based on Terrain Observation with Progressive Scans SAR (TOPSAR) (De Zan and Monti Guarnieri, 2006). In IW mode,
 SAR images are divided in three swaths, each swath being made of Single Look Complex (SLC) tiles called bursts (Torres et
 al., 2012). Interferometric processing of Sentinel-1 IW acquisitions requires some specific processing steps, such as
 deramping or burst stitching, that are explained in Yague-Martinez et al. (2016).

Let us consider a repeat-pass interferogram computed with a master image acquired at epoch t^i and a slave image acquired
 125 at epoch t^j . After subtraction of the flat earth and topographic phase components, the phase in the interferogram can be
 expressed as a sum of the following phase components:

$$\phi^{ij} = \phi_{flow}^{ij} + \phi_{tides}^{ij} + \phi_{defo}^{ij} + \phi_{noise}^{ij}, \quad (1)$$

where ϕ_{flow}^{ij} is the ice flow motion phase component, ϕ_{tides}^{ij} is the tidal phase component, ϕ_{noise}^{ij} is the random phase noise
 and ϕ_{defo}^{ij} accounts for any deformation or displacement that does not originate from ice flow or tidal deformations, e.g.
 130 iceberg drift, mechanical stress or structural deformation. In the following, for the sake of simplicity, we assume that the
 phase noise is negligible. While the tidal component is determined by the change of the vertical position \bar{D}_{tides}^{ij} of the ice
 shelf between epochs t^i and t^j resulting from the balance between oceanic tides and atmospheric pressure (Padman et al.,
 2003), the ice flow motion phase component is proportional to the surface ice velocity vector \vec{v}^{ij} projected on the line-of-
 sight (LOS) v_{los}^{ij} and the temporal baseline $\Delta t^{ij} = t^j - t^i$ of the interferometric pair. Similarly, the

135 deformation/displacement phase component is also determined by the projection d_{los}^{ij} of the 3D displacement vector \vec{d}^{ij} on the LOS direction. Each components is exemplified by a sketch in Fig. 2. According to the situations illustrated in Fig. 2, the different phase components can be expressed as:

$$\phi_{flow}^{ij} = \frac{4\pi}{\lambda} v_{los}^{ij} \Delta t^{ij}, \quad (2)$$

$$\phi_{tides}^{ij} = \frac{4\pi}{\lambda} D_{tides}^{ij} \cos \theta, \text{ and} \quad (3)$$

140 $\phi_{defo}^{ij} = \frac{4\pi}{\lambda} d_{los}^{ij}, \quad (4)$

where θ is the local incidence angle.

145 **Figure 2: Displacements and deformations contributing to the interferometric phase over an ice shelf. (a) Change of vertical position caused by tidal bending. (b) Horizontal ice flow motion. (c) Ice shelf deformation. The ice shelf is represented at times t^i and t^j respectively by the continuous and dashed blue lines.**

In practice, interferograms over an ice shelf exhibit a clear segmentation of the fringe pattern, with discontinuities corresponding to the rifting system. This has already been observed in several cases for different ice shelves – e.g. Brunt, Larsen-C, or Ronne ice shelves (Rignot and MacAyeal, 1998; Larour et al., 2004; Hogg and Gudmundsson, 2017; De Rydt et al., 2018) and it is further illustrated in this paper for Brunt Ice Shelf. In Fig. 1, the rifting system of BIS is pictured and compared to a repeat-pass interferogram generated from Sentinel-1 images acquired 6 days apart in September. We observe that active cracks, rifts and chasms correspond to phase discontinuities in the fringe pattern, dividing the ice shelf into regions with different fringe rates and fringe orientations. As highlighted by Eq (1), the segmented fringe pattern suggests

150

that SAR interferometry captures a spatially discontinuous ice flow velocity, tidal response and mechanical stress field created by rifting activity.

155 In the region of BIS, the vertical position of the floating ice, determined by the amplitude of oceanic tides and the variation of atmospheric pressure, may vary by more than 1 m between acquisitions 6 days apart. However, away from the grounding line, the change of vertical position for a given pair of acquisitions shows smooth spatial variations of only a few centimeters. In comparison, the ice flow can reach velocities up to 2.5 m d^{-1} (ENVEO CryoPortal), partially captured by the LOS orientation. As a consequence, the tidal phase component corresponds to largely spaced fringes, and the phase signal is
 160 dominated by the ice flow motion contribution.

The segmentation of the interferogram into regions with distinct phase ramps related to the rifting activity constitutes the basis of the method presented in the following for delineating cracks automatically. Because the response of ice shelves to rifting and the mechanisms driving the crack propagation are still poorly understood, we assume that all phase contributions can have a spatially discontinuous behaviour and the crack detection is performed on interferograms containing the
 165 information of all three phase components. Let us note that, in the following, we will refer to repeat-pass interferograms whose flat earth and topographic phase components have been subtracted as *differential interferograms*, or simply *repeat-pass interferograms*. The terminology *double difference interferogram* will be used for interferograms computed as the difference of two differential interferograms.

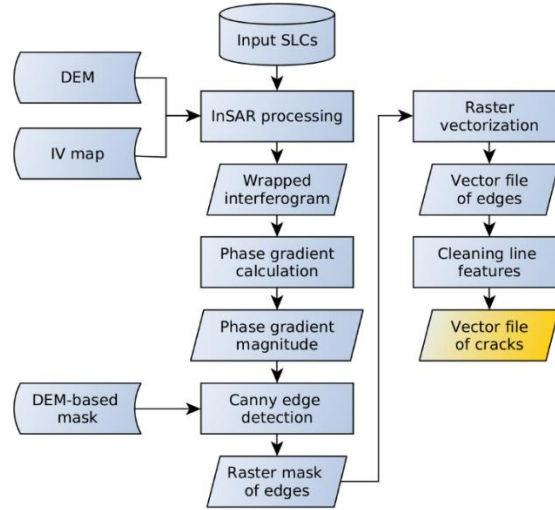

4 Method

170 To achieve an automatic delineation of active cracks on ice shelves, we propose a method that aims at detecting discontinuities in the phase image. The method consists of four major steps: 1) the generation of a repeat-pass differential interferogram, 2) the derivation of the phase gradient map, 3) a Canny edge detection applied to the image of the phase gradient magnitude, and 4) the vectorization and cleaning of the edge detection results. The processing line is presented in Fig. 3. The flowchart describes the input data, the auxiliary data, the processing steps and the output product of each step. In
 175 the following, each processing step is described in detail and exemplified using the Sentinel-1 interferogram of BIS shown in Fig. 1. The intermediate products corresponding to this example are provided in Fig. 4 and 5, together with close-up views of the North Rift.

First, Sentinel-1 repeat-pass interferograms are generated from IW SLC acquisitions according to the method presented in Andersen et al. (2020), which is optimized for ice velocity measurements with TOPSAR interferometry. Due to the steering
 180 of the antenna from the aft to the fore during each burst acquisition, hence introducing different viewing angles at the overlap of one burst and the next, Sentinel-1 repeat-pass TOPSAR interferograms may suffer from phase jumps caused e.g. by along-track ice motion (De Zan et al., 2014). Furthermore, ice flow motion, especially in fast-flowing regions, shifts phase centers of the slave image with respect to their location in the master image, leading to potential decorrelation. In addition to account for the precise state vectors, the coregistration procedure compensates for the local shifts between the

185 master and slave burst SLCs caused by the along-track and across-track ice flow components, derived e.g. from offset-tracking, in order to reduce phase jumps and improve the coherence. After coregistration of the master and slave burst SLCs, the interferogram is generated at the burst level, the flat earth and topographic phase components are subtracted and the burst interferograms are stitched together to form an area-wide differential interferogram.

190 **Figure 3: Processing line for automatic delineation of cracks with InSAR.**

The phase signal in the interferogram is a sum of the ice motion component, the tidal component and the random phase noise, that results in distinct phase ramps throughout the ice shelf corresponding to separate regions of the rifting system (Figure 1). The wrapped differential interferogram is geocoded and subsequent processing steps are applied to the geocoded fringes.

195 In the second step, the phase gradient is calculated pixelwise for each geocoded differential interferogram. Given $\phi_{k,l}$ the value of the wrapped phase for a pixel with coordinates (x_k, y_l) in the interferogram, k and l being the discretization indices in the x- and y-directions respectively, the phase gradient is written as

$$\vec{\nabla}\phi(x_k, y_l) = \left(\frac{\partial\phi}{\partial x}, \frac{\partial\phi}{\partial y} \right) \Big|_{(x_k, y_l)}. \quad (5)$$

The temporal indices i and j are here omitted for the sake of readability. The x- and y-directions refer to the axes of the map projection, which is the Antarctic Polar Stereographic projection (EPSG 3031) in this case. The discrete phase derivatives are computed by averaging the phase differences between adjacent pixels along the x- and y-directions over a square window with an odd size of w pixels. The averaging is performed using the complex representation of the phase, as expressed by

$$\frac{\partial\phi}{\partial x} \Big|_{(x_k, y_l)} \simeq \angle \left[\sum_{j=k-\frac{w-1}{2}}^{k+\frac{w-1}{2}} e^{i(\phi_{j+1,l} - \phi_{j,l})} \right], \text{ and} \quad (6)$$

$$\left. \frac{\partial \phi}{\partial y} \right|_{(x_k, y_l)} \simeq \angle \left[\sum_{j=l-\frac{w-1}{2}}^{l+\frac{w-1}{2}} e^{i(\phi_{k,j+1}-\phi_{k,j})} \right], \quad (7)$$

205 where \angle represents the argument of the complex exponential. Equations (6) and (7) provide a phase variation per pixel, assuming that pixels are square. If the aspect ratio of the pixel is different than one, then a scaling factor should be applied.

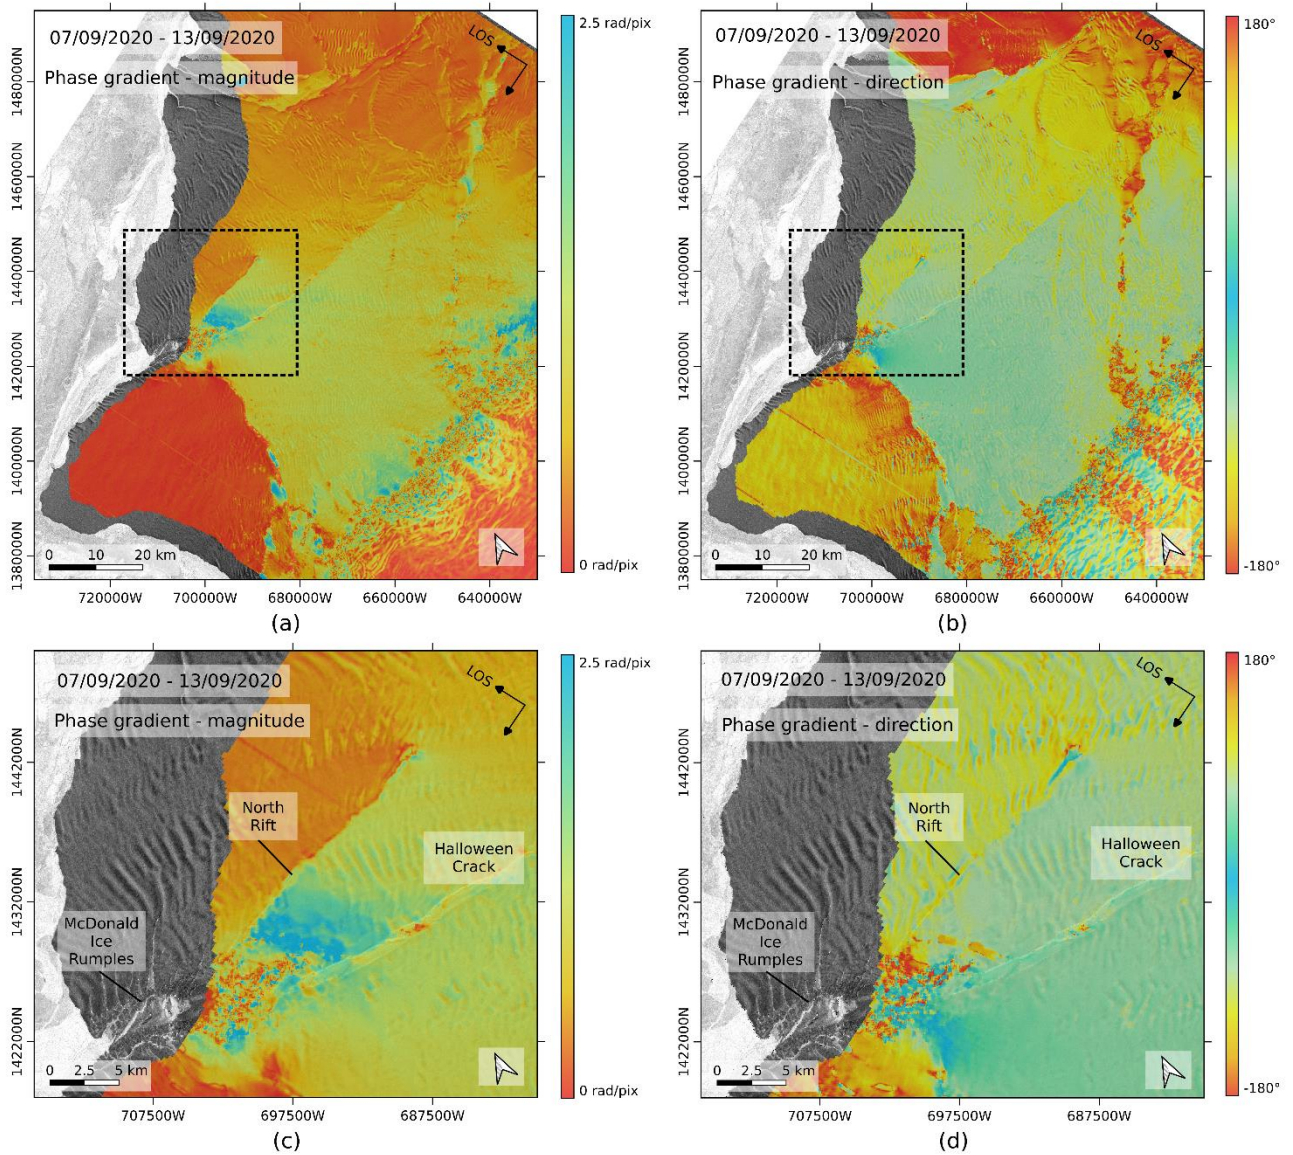

Figure 4: Phase gradient of the interferogram of 7–13 September 2020 shown in Fig. 1(b). (a) magnitude of the phase gradient. (b) direction of the phase gradient, with angles calculated positive counterclockwise with respect to the horizontal axis. (c) Close-up view of (a), whose extent is indicated by the black dashed frame. (d) Close-up view of (b).

215 The calculation of the phase gradient translates the complex information provided by the spatially variable fringe pattern into a two layer real image (i.e. the x- and y- components corresponding to the projection axes in the cartesian case, the gradient magnitude and angle in the polar case). Moreover, by computing the phase gradient directly from the wrapped phase (expressed as a complex number), the tedious step of phase unwrapping is avoided, as well as the phase artifacts that it may introduce.

In practice, the phase gradient is converted to a polar vector, whose magnitude holds the information about the local fringe rate and whose angle indicates the direction of the phase ramp. For the demonstration case, the images of phase gradient magnitude and angle are shown respectively in Fig. 4(a) and 4(b). In both the magnitude and direction images, the location of the phase discontinuities, i.e. the active cracks, is enhanced and has become easy to identify (e.g. North Rift, Chasm 1 or Brunt–Stancomb Chasm). For most of the identified rift structures, the edges in the magnitude and direction images indicate similar locations. However, for wide open chasms with a complex structure (e.g. the widest part of Chasm 1 or the Brunt–Stancomb Chasm), the magnitude and direction of the phase gradient may picture a slightly different fractured area. Given that the crack locations mapped by both indicators are mostly similar and that the angles are wrapped by nature, which makes them difficult to manipulate, we neglect the phase gradient direction and focus on the information held by the phase gradient magnitude.

225 In the phase gradient magnitude image, active cracks correspond generally to a well-defined step-edge with variable contrast. Crack delineation is hence performed by applying a Canny edge detection to this image (Canny, 1986). In order to reduce the noise while preserving the edges, a median filter is applied beforehand. In practice, the Canny edge detection consists of computing the intensity gradient of the input image and applying a double threshold for mapping the edges: the upper threshold discriminates the strong edges; the lower threshold is used for selecting the weak edges, meant to connect the strong edges present in their neighborhood. An additional Gaussian filtering, with tunable standard deviation, is performed as part of the Canny edge detection procedure for reducing the noise while computing the intensity gradient.

235 We focus on the rifting activity on the ice shelf and therefore mask the areas of grounded ice. The masking is performed with a simple thresholding of the TanDEM-X global digital elevation model at a 50 m height, that shows a rough agreement with the grounding line location. Patchy decorrelation can also cause erroneous edge detection and areas with low coherence (< 0.12) are therefore also excluded.

As shown by the blue lines in Fig. 5, applying the Canny edge detection to the gradient magnitude efficiently maps the cracks present on BIS. However, it also maps small “dangles” (loose curvy lines) caused by phase artifacts, topography or crevasses. As a final step, the raster mask generated by the Canny edge detection module is thinned, vectorized and cleaned using GRASS GIS tools. The cleaning consists of removing small dangles, as they are less likely to correspond to a major propagating crack. The cleaning step is critical and the result should be carefully evaluated, because poor thresholds can lead to a substantial loss of detectable cracks. Though necessary for removing noise and obtaining readable information, the cleaning process sets a bound on the minimum size of detectable cracks, depending on the dangle size threshold.

As shown by the red lines in Fig. 5, the noisy aspect is reduced after the cleaning step. Some residual errors remain, especially in the region near the grounding line. This area is highly crevassed due to the tidal bending and the rapid height change at the transition between floating and grounded ice. These residual dangles thus correspond to a damaged area, though crevasses are not the damage that we aim at mapping. Future studies might investigate the density of detected edges in the vicinity of the grounding line as an indication of the degree of crevasse damages.

Although the InSAR-based crack delineation performs well under conditions that preserve the phase coherence, its applicability is primarily limited by the quality of the SAR interferogram. In case of fast-flowing ice, snowfall, surface melt or snow drift caused by katabatic winds, the InSAR signal decorrelates and the method cannot be applied. Even so, the regularity of Sentinel-1 acquisitions offers an increased likelihood of coherent interferometric pairs. Another limitation directly originates from TOPSAR interferometric processing, which is strongly affected by coregistration errors, uncorrected ionospheric delays and uncompensated tidal displacements, that may leave residual phase discontinuities at the burst overlap (e.g. see the western tip of the ice shelf in Fig.1(b)), hence causing potential false detections (De Zan et al., 2014).

Let us note that, in the illustrating example, the Halloween crack is only partially mapped even though it is visible in the brightness images. The fringe pattern is similar on both sides of the crack and the corresponding gradient discontinuity appears faint in the gradient image, which might indicate that the rift was inactive during the investigated time period.

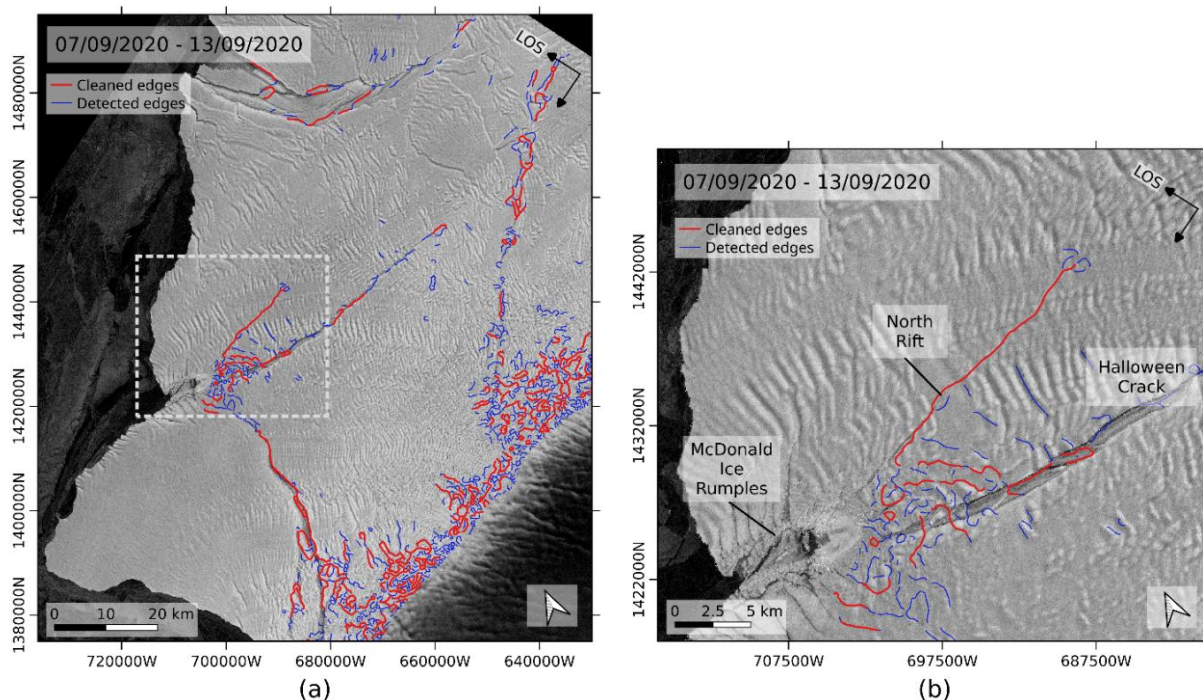

Figure 5: Cracks automatically delineated from the interferogram of 7–13 September 2020. (a) Edge detection results, before (blue) and after cleaning (red) of the small dangles. The Canny edge detection applied to the phase gradient magnitude shown in Fig. 4. (b) Close-up view of (a), whose extent is indicated by the gray dashed frame.

5 Dataset and processing

To capture the propagation of the North Rift and the calving of A74, the InSAR-based method for crack delineation is tested on a dataset of Sentinel-1 SLC images acquired every 6 days between 1 September 2020 and 6 March 2021, along track 50 (Figure 6). We selected the frames covering BIS and generated all available 6-day repeat-pass interferograms. Overall, 32 interferograms were generated, out of which 9 could not be used for crack delineation because of signal decorrelation. In particular, the interferograms spanning the periods directly before and after the calving event (i.e. between 10 February 2021 and 6 March 2021) could not be used for mapping the North Rift with InSAR. Because the amount of fringes caused by ice motion increases with the temporal baseline, most of the Sentinel-1 interferometric pairs acquired along track 164, with 12-day repeat pass, were decorrelated. Given their limited quality and temporal resolution, these pairs are not used for crack delineation, but only to support the interpretation and analysis of the temporal evolution of fracturing.

Figure 6: Sentinel-1 coverage of BIS: track 50 (red) and track 164 (blue). The background is a shaded relief of REMA DEM (Howat et al., 2019). In IW mode, incidence angles vary from about 30° in the near-range to 45° in the far-range.

In order to reduce the phase noise, the interferograms are computed with a multilooking factor of 9 x 3 pixels in the slant range and azimuth directions, respectively, and an adaptive Goldstein filtering is applied for further noise reduction (Goldstein and Werner, 1998; Baran et al., 2003). For the coregistration, the average ice flow motion is compensated using a multiannual ice velocity map with 200 m pixel spacing generated within the ESA Antarctic Ice Sheet CCI project (ESA Climate Office: Ice Sheets Antarctic). The Antarctic velocity map is calculated using offset-tracking applied to all Sentinel-1 6- and 12-day repeat pairs available for the mission lifetime (2014–today). The offset-tracking processing is described in Nagler et al. (2015), and an additional correction of the vertical displacement induced on floating ice by differential tides (CATS2008; Erofeeva et al., 2019) and atmospheric pressure (ERA-5; C3S, 2017) is applied to offset-tracking results. The topographic phase is estimated and subtracted from the repeat-pass interferograms using the TanDEM-X polar DEM with 90

285 m grid resolution, extended to cover ice shelves (Wessel et al., 2021). Finally, the interferograms are geocoded on a grid with a 40 m pixel spacing in the Antarctic Polar Stereographic reference system, that matches approximately the pixel size in the radar geometry.

For each geocoded repeat-pass interferogram, the phase gradient is calculated over a 9 x 9 pixel window and the image of the phase gradient magnitude is further filtered using a median kernel of 9 x 9 pixels. The Gaussian kernel has a standard
290 deviation equal to 5, and the lower and upper thresholds for edge detection are set respectively to 0.15 and 0.21. Furthermore, all areas above 50 m height or having a coherence lower than 0.12 are masked out for the edge detection procedure. The raster output of the edge detection is thinned, vectorized and cleaned by applying a threshold of 2000 m on the dangle size.

6 Results and discussion

295 6.1 Interferogram time series

The sensitivity of Sentinel-1 repeat-pass interferograms to the North Rift propagation is illustrated by a time series of interferograms presented in Fig. 7. These differential interferograms are all acquired along track 50 and computed as described in the previous section. The black dashed line represents the manually delineated calving front location, after the calving event of A74, and it is used to picture the North Rift's maximum extent. In this figure, it is visible that the
300 discontinuity line expands along the crack location from one interferogram to the other. The magnitude and direction of the phase gradient is highly variable and provides a first qualitative indication of the propagation timeline of the North Rift: in November 2020, the rift propagates as a straight line in a given direction and the phase ramp on the northern side of the rift varies gently; at the end of December, after a complete rotation of the fringe pattern, the crack changed direction to propagate toward the Brunt–Stancomb Chasm; at the end of January, when part of the northern plate is decorrelated and the
305 fringe pattern is very tight, it is visible that the crack almost reached the chasm.

6.2 Automatic delineation

The proposed InSAR-based method for crack delineation is applied as described in the previous section to produce a time series of vector files mapping the BIS crack system with a 6-day resolution, only interrupted whenever the interferometric phase is decorrelated. Though a rough estimate could already be obtained from the visual analysis of the interferogram time
310 series, the automatically delineated cracks enable a refined and more objective determination of the North Rift propagation from the start of the crack propagation until the calving of A74. In Fig. 8, some selected repeat-pass interferograms are displayed at a larger scale together with the phase gradient vector field and the automatically delineated cracks. It is seen that the North Rift started to open up a few kilometers between 18 and 24 November 2020. Indeed, the phase discontinuity indicated by the yellow line expands between 12–18 November 2020 and 18–24 November 2020. Around the expanding end
315 of the crack, we observe a rotation of the phase gradient that corresponds to a change in the stress field. Compared to the

November interferograms, the interferogram of 18–24 December 2020 shows a 1.5 to 2.5-fold intensification of the phase ramp around the rift and a change in direction. At this date, the crack already changed direction, after propagating on several tens of kilometers eastward.

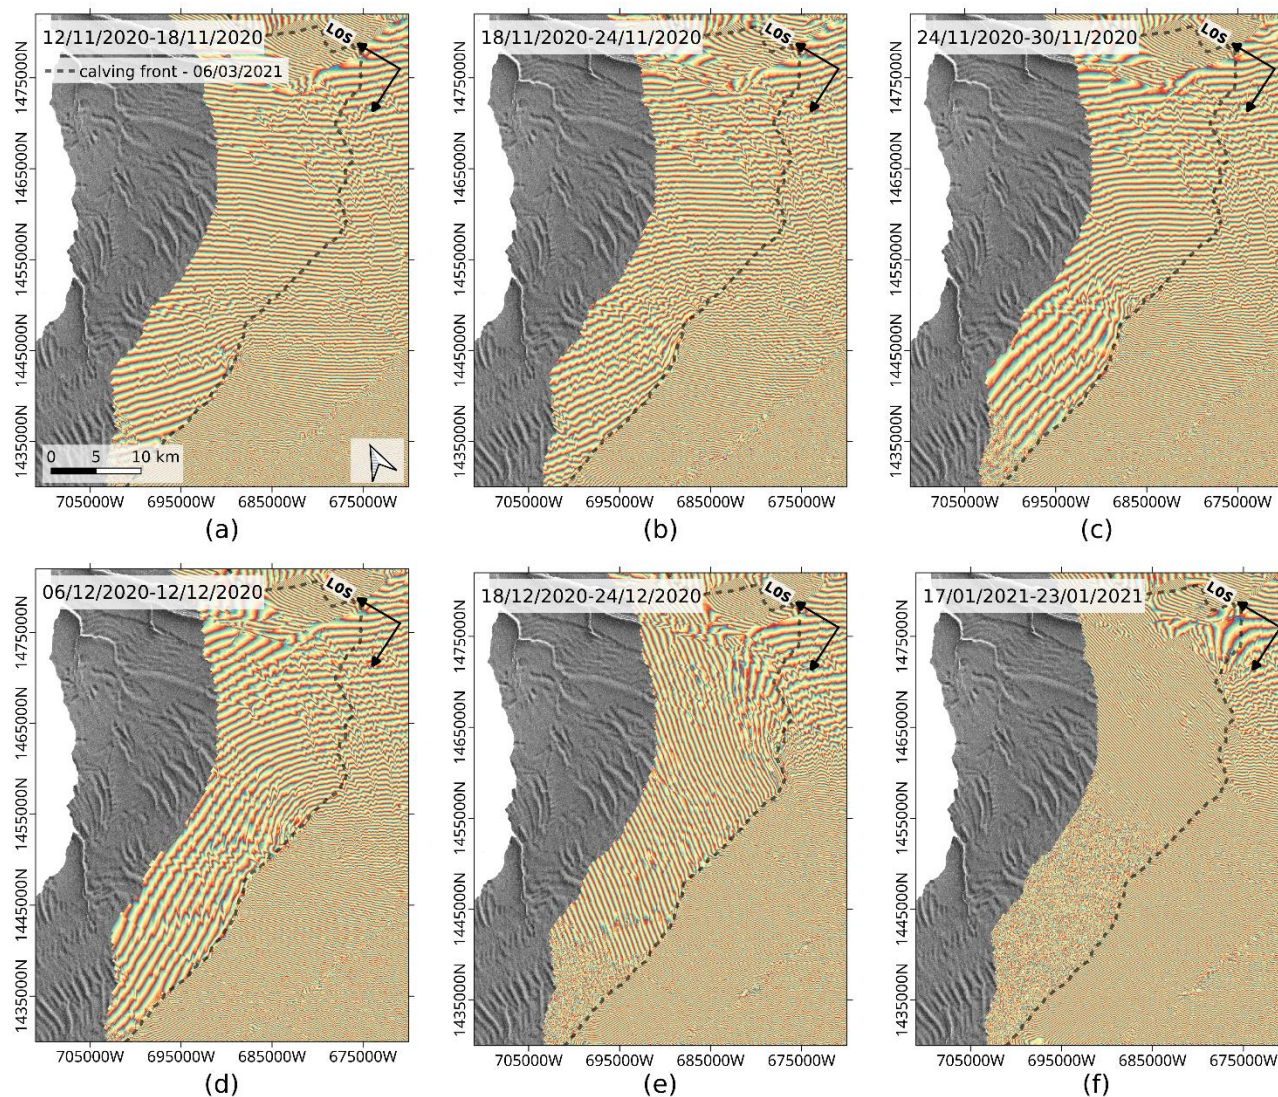

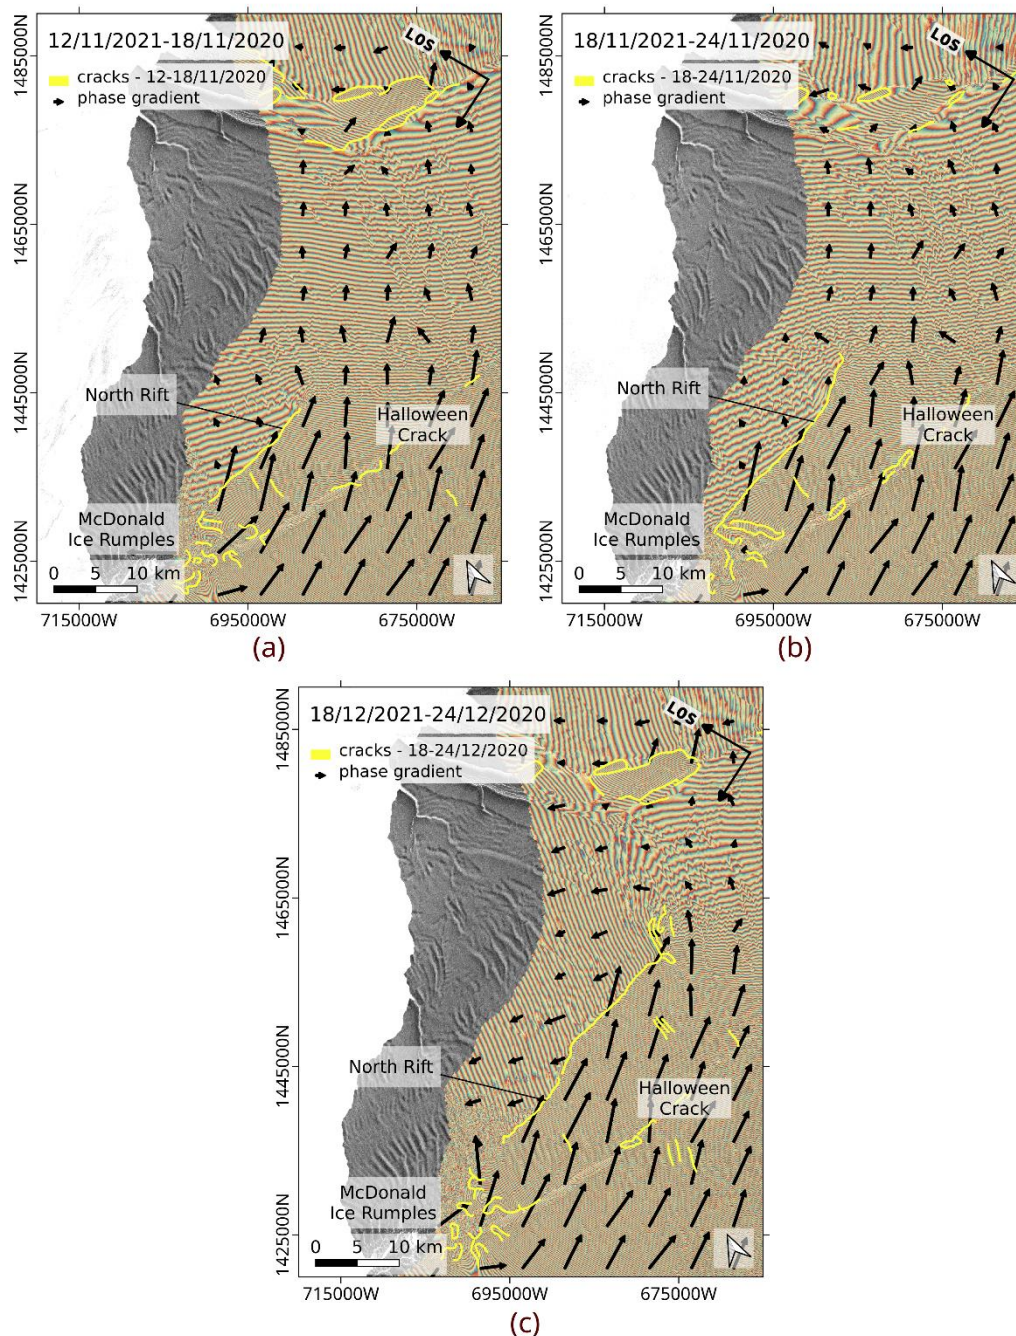

Figure 7: Time series of wrapped repeat-pass interferograms showing the phase ramp variation from one date to another, as the North Rift propagates between November 2020 and January 2021. The black dashed line indicates the full extent of the North Rift, manually delineated from the calving front on 6 March 2021, after the A74 formed.

325 **Figure 8: Sentinel-1 repeat-pass interferograms on BIS, overlaid with the cracks delineated from the phase gradient magnitude (yellow lines). The phase gradient is pictured by the vector field. (a) 12–18 November 2020. (b) 18–24 November 2020. (c) 18–24 December 2020. The comparison of the interferograms shows a rapid propagation of the North Rift between 18 and 24 November 2020. In December 2020, the crack almost reached the Stancomb–Wills Chasm. As the crack propagates, the phase gradient intensifies and changes direction on both sides of the rift.**

330 The propagation history is summarized in Fig. 9, where automatically delineated cracks representing the major steps of the North Rift advance are shown. This figure results from a selection of the relevant dates and the coherent interferograms in the processed dataset. The background is a Sentinel-1 brightness image acquired on 6 March 2021, that shows a good agreement between the delineated cracks and the calving front after the iceberg A74 formed. As already stated above, the crack started to open sometime between the 18 and 24 November 2020, and continued to rapidly propagate in early
 335 December. As the rift opened, both sides of the crack slowly drifted away from each other, leading to a massive coherence loss on the northern side of the rift and some erroneous detections after mid-December. Despite the phase noise, the crack delineation method was able to map the easternmost part of the North Rift and the results agree well with the shape of the manually derived calving front. From the interferogram of 17–23 January 2021, about a month before the iceberg broke off, the quasi-full extent of the calving could already be mapped.

340

Figure 9: Propagation history of the North Rift between 7 September 2020 and 23 January 2021, from automatically delineated cracks. Significant dates have been selected. The delineated cracks are overlaid on a Sentinel-1 brightness image acquired on 6 March 2021, showing the calving front shape after the iceberg A74 formed.

6.3 Propagation rates

345 In addition to the delineation, the North Rift length is also estimated for the selected dates and the evolution of the rift length over time is plotted in Fig. 10. The crack length is estimated as the cumulative length of the delineated segments corresponding to the North Rift. In the case of incomplete or interrupted segments, e.g. due to decorrelation, the missing

segment length is estimated manually. As expected, the estimated length consistently grows over time, except for the pair of
 12–18 November 2020, whose crack extent is estimated to be smaller by about a hundred meters compared to the earlier pair
 of 7–13 September 2020. This inconsistency stresses the inaccuracy of the estimation method, that is used for analysis
 purposes rather than accurate quantitative estimates. Based on the estimated crack extent, the propagation rates are derived as
 the segment slope between two consecutive points (see the annotated values in Fig. 10). The propagation rate is the largest
 (about 1.3 km d^{-1}) when the North Rift activates at the end of November and reaches a similar value at the latest stage of
 propagation in January. In between, the progress of the North Rift extent is in the order of several hundred meters per day.

Figure 10: North Rift propagation rates.

6.4 Comparison with SAR backscatter imagery

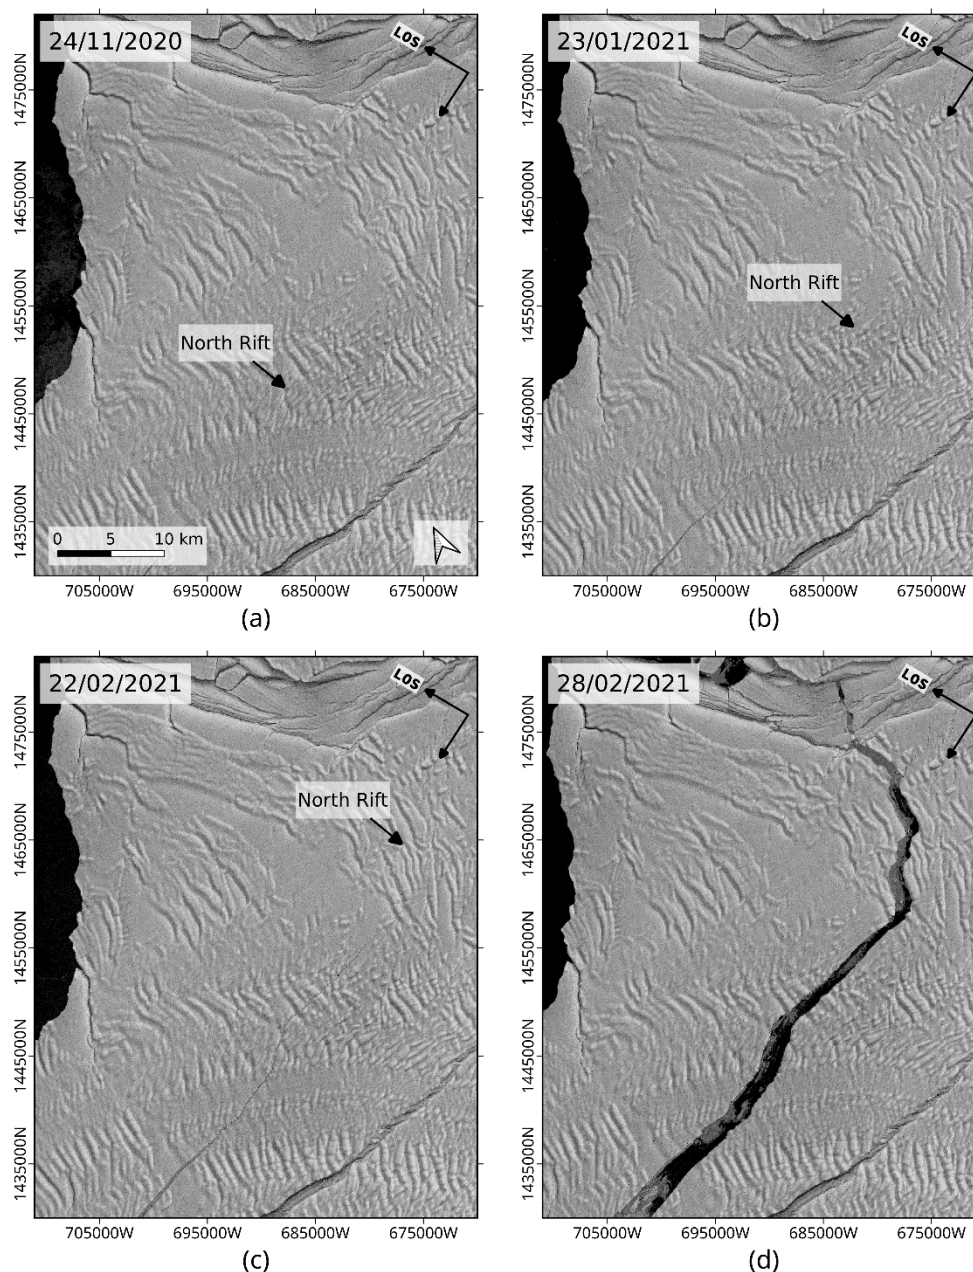

In order to stress the added value of SAR interferometry for mapping active rifts, we present in Fig. 11 the evolution of the
 North Rift as seen with a time series of Sentinel-1 backscatter images. While SAR interferometry is sensitive to sub-
 centimeter deformations between two epochs, SAR backscatter imagery characterizes the static situation at a given time.
 Furthermore, its application to crack monitoring is limited by the image resolution and the lack of backscatter contrast over
 thin cracks. In the brightness images, the North Rift is visible in November, but shows a relatively small extent compared to
 that mapped with interferometry (see interferograms in Fig. 7). The well-advanced breach is visible in the brightness images
 only a few days before the calving of the iceberg. Comparatively, the interferogram of 17–23 January 2021, fully captures
 the extent of the crack that becomes visible only a month later in the brightness image acquired on 22 February 2021.

6.5 Stress field variations

The discontinuity of the fringes constitutes the assumption behind mapping active cracks with SAR interferometry and the
 variability of the phase gradient magnitude and orientation has been illustrated in Fig. 7 and Fig. 8. However, the origin of

these temporal variations remains difficult to determine from differential interferograms, as the differential phase is a
 370 combination of ice flow, ice deformation and intrinsically variable tidal displacements (see Eq. (1)). Temporally variable
 components of the phase signal can be isolated by computing differences between repeat-pass interferograms.

**Figure 11: Propagation of the North Rift between end of November and end of February observed with a series of Sentinel-1 radar
 375 brightness images. The iceberg A74 formed on 26 February 2021. The images focus on the same area as the interferograms in Fig.
 6. (a) 24 November 2020. (b) 23 January 2021. (c) 22 February 2021. (d) 28 February 2021.**

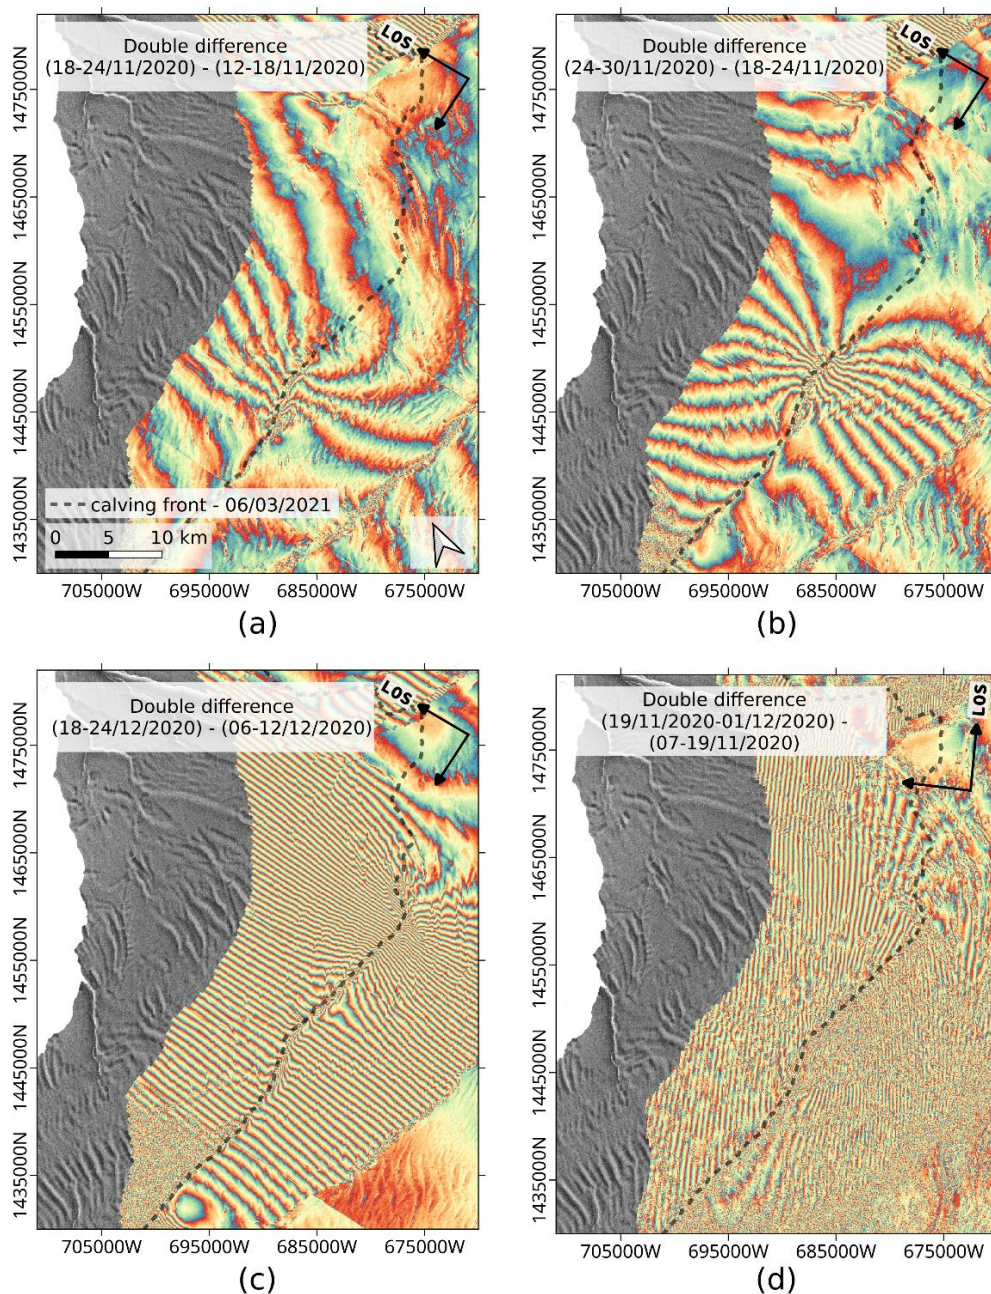

Figure 12: Difference between consecutive repeat-pass interferograms showing the stress field variation as the North Rift propagates. (a)-(c) are calculated from 6-day interferograms of track 50 shown in Fig. 7. (c) is calculated from 12-day interferograms of track 164 (not shown). The black dashed line indicates the full extent of the North Rift. (a) Difference between 18–24 November 2020 and 12–18 November 2020 (track 50). The crack starts to propagate. (b) Difference between 24–30 November 2020 and 18–24 November 2020 (track 50). The crack propagates as a straight line along a given direction. (c) Difference between 18–24 December 2020 and 6–12 December 2020 (track 50). The crack has almost reached the Stancomb–Wills Chasm. (d) Difference between 19 November–1 December 2020 and 7–19 November 2020 (track 164). The crack has reached its diverging point.

385 To highlight the variable phase contributions, Equations (2)–(4) can be reformulated in terms of the variation with respect to the bulk contributions of the ice flow velocity v_{los}^{bulk} , tidal vertical displacement D_{tides}^{bulk} and deformation d_{los}^{bulk} :

$$\phi_{flow}^{ij} = \frac{4\pi}{\lambda} (v_{los}^{bulk} + \Delta v_{los}^{ij}) \Delta t^{ij}, \quad (8)$$

$$\phi_{tides}^{ij} = \frac{4\pi}{\lambda} (D_{tides}^{bulk} + \Delta D_{tides}^{ij}) \cos \theta, \text{ and} \quad (9)$$

$$\phi_{defo}^{ij} = \frac{4\pi}{\lambda} (d_{los}^{bulk} + \Delta d_{los}^{ij}), \quad (10)$$

390 A double difference interferogram computed from two repeat-pass interferograms spanning respectively epochs t^i, t^j and t^m, t^n has a phase $\Delta\phi^{ij,mn}$ written as:

$$\Delta\phi^{ij,mn} = \phi^{mn} - \phi^{ij}. \quad (11)$$

Thanks to the almost exact repeat orbit of Sentinel-1, the line-of-sight direction and the incidence angle can be assumed to be constant for all interferograms along a given track. The phase difference can therefore be calculated easily using repeat-pass
 395 interferograms geocoded on a common grid. If the repeat-pass interferograms have the same temporal baseline, i.e. $\Delta t^{ij} = \Delta t^{mn} = \Delta t$, inserting Eqs. (8)–(10) into Eq. (11), the phase of the double difference interferogram can be formulated as:

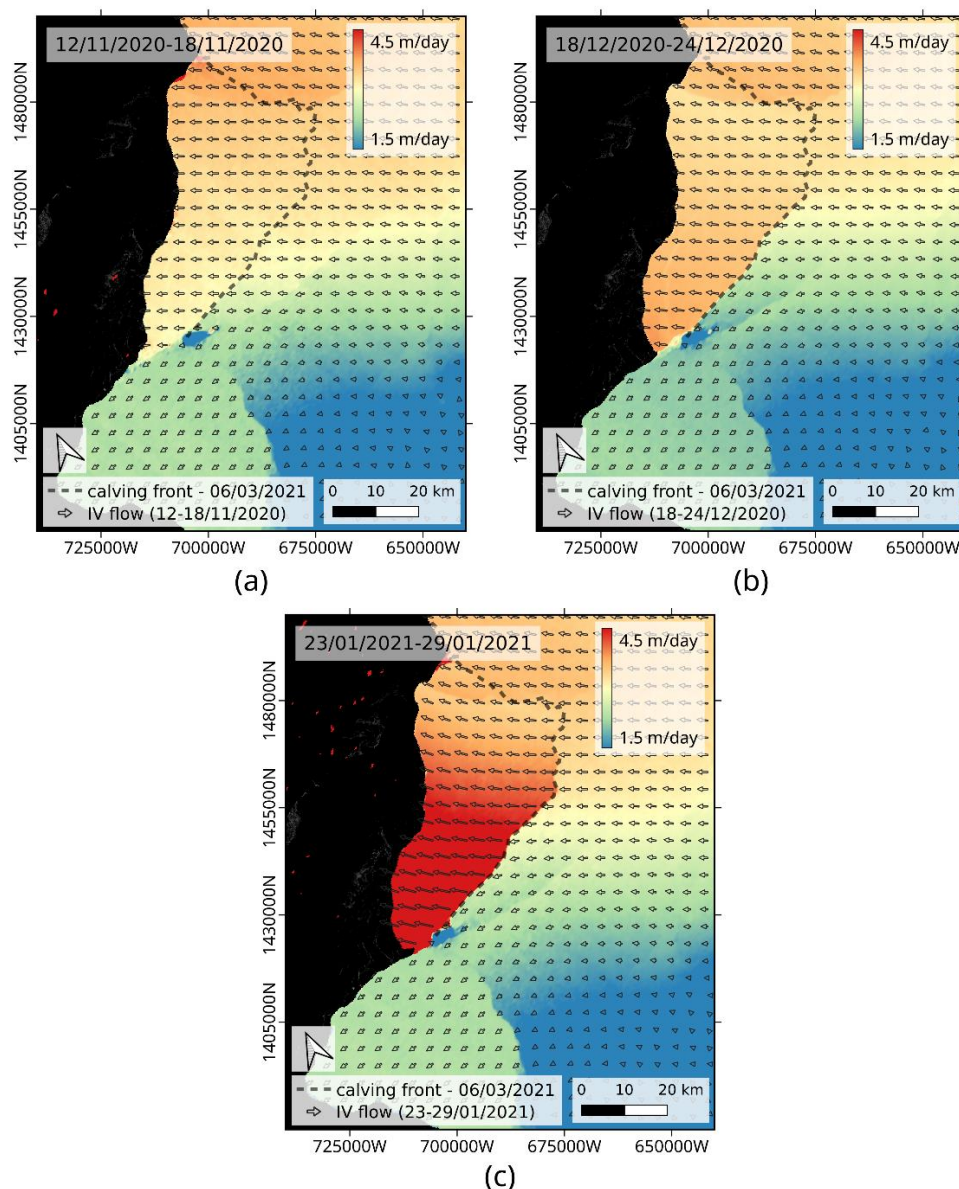

$$\Delta\phi^{ij,mn} = \frac{4\pi}{\lambda} [(\Delta v_{los}^{mn} - \Delta v_{los}^{ij}) \Delta t + (\Delta D_{tides}^{mn} - \Delta D_{tides}^{ij}) \cos \theta + (d_{los}^{mn} - d_{los}^{ij})]. \quad (12)$$

Equation (12) shows that the differentiation of two interferograms with the same temporal baseline removes the bulk contribution of the ice flow velocity, the oceanic tides and the mechanical stress field. In the absence of ice flow speedup and
 400 other deformations than the tidal ones, the double difference interferogram contains only the change of tidal bending between 4 epochs (3 epochs in case of a common date) (Rignot and MacAyeal, 1998). Nevertheless, if the ice shelf undergoes changes in flow velocity or creep deformation, such differentiation would remove the bulk contributions of the ice flow and of the tidal deformation, leaving only the natural variations caused by the change of tidal amplitude and the deformation between 4 (or 3) epochs, caused e.g. by rifting activity.

405 For isolating the temporally variable component of the phase signal introduced by rifting activity, differences between consecutive 6-day repeat-pass interferograms along track 050 are computed. These double difference interferograms are shown in Fig. 12. The first one is the difference between the interferograms of 12–18 November and 18–24 November 2020. It shows curved fringes on the expanding tip of the crack, likely caused by the mechanical stress of the diverging ice plates as the crack starts to propagate. In the second double difference interferogram (18–24 November and 24–30 November
 410 2020), the stress field becomes almost evenly distributed on both sides of the rift (14 fringes on the north plate and 12 on the south plate). This number of fringes corresponds to a displacement of about 35 cm in the direction of the line-of-sight, which is almost parallel to the fringe orientation. Finally, in December 2020, when the crack propagation changes direction, the fringe pattern becomes very tight and remains almost evenly balanced on the north and south plates. Without the information

from another viewing direction, the observed phase ramp could either correspond to a vertical deformation or to a horizontal
 415 displacement. For solving this ambiguity, we also display the difference between 12-day interferograms acquired in
 November along the opposite direction (track 164). Interferograms along this orbit have a lower temporal resolution and
 quality, and they are therefore only used here to support the analysis. The double difference results in this case into a
 homogeneous fringe pattern with fringes oriented nearly parallel to the crack.

420 **Figure 13: Ice velocity field over BIS calculated with offset-tracking applied to Sentinel-1 6-day pairs over track 50. The background image is the magnitude of the ice velocity and the overlaid vector field represents the ice flow vector. The results are corrected for vertical tidal displacements using the CATS2008 model for tides and the ERA-5 model for atmospheric pressure. (a) 12–18 November 2020. (b) 18–24 December 2020. (c) 23–19 January 2021.**

For both tracks, the double difference interferograms show fringes nearly parallel to the line-of-sight direction around the North Rift. Peltzer et al. (1994) simulated the fringe pattern due to a rigid-body rotation around an axis that is perpendicular to a horizontal surface and demonstrated that it would create such fringes parallel to the viewing direction. Later on, Rignot and MacAyeal (1998) also observed fringes parallel to the LOS direction on Ronne Ice Shelf and interpreted it as rigid-body rotation around an axis perpendicular to the ice shelf surface and located at the tip of the crack. Because they observed this pattern in the differential interferograms but not in the double difference ones, they attributed this rigid-body rotation to a velocity difference between both sides of the rift, not to a transient phenomenon. In the case of the North Rift, fringes parallel to the line-of-sight are observed with two different viewing directions and a rigid-body rotation around the tip of the crack seems therefore likely. Since this pattern is present in the double difference interferograms, it would be in this case associated to a time-varying response to rift propagation that dominates the variation of vertical tidal displacements.

The hypothesis of the rigid body rotation is further strengthened by ice velocity measurements performed with offset-tracking and shown in Fig. 13. The offset-tracking measurements show an acceleration of the ice flow around the southwest part of the North Rift from December 2020 onwards. Simultaneously with the North Rift propagation in November–December, a speedup of about 0.5 m d^{-1} is measured on the tip of the northern plate. In January, the measured velocity further increases to reach a speedup of about 2 m d^{-1} on the tip. The amplitude of the speedup varies from the southwest to the northeast, similarly to the stress field observed in the double difference interferograms, and this acceleration comes together with a rotation of the velocity vector field towards the northeast and southwest directions respectively north and south of the rift. The change in orientation of the measured velocity field fits indeed with a clockwise rotation around the tip of the North Rift. Although this could originate from ice flow speedup due to the loss of constraint at the MIR, it could also be caused by a drift/rotation of the whole iceberg that would be misinterpreted as ice flow acceleration by offset-tracking.

7 Conclusion

The InSAR-based method proposed for automatic crack delineation has been successfully tested and qualitatively validated on BIS with a dataset of Sentinel-1 6-day repeat-pass interferograms spanning a period of 6 months. The applicability of the method has been demonstrated by tracing the propagation history of the North Rift, from the rift activation up to the calving of the iceberg A74.

For the North Rift, the shape of the delineated crack agrees well with the calving line location after the iceberg calving, thereby demonstrating the suitability of the approach. In general, phase artifacts in the interferograms may introduce noise in the delineated cracks, but the InSAR-based method is still less impeded by topography and structural heterogeneity of the ice shelf than SAR backscatter imaging. A limiting factor of the method is the decorrelation caused by snow drift, snow melt or fast-flowing ice, as it prevents any InSAR measurements.

In addition to the propagation history, the temporally variable phase contribution could be isolated and interpreted as rigid-
 455 body rotation about the expanding tip of the North Rift in response to the rifting activity. Without further information, it is
 not possible to determine whether the rotation origin is an ice flow speedup or ice drift.

Combined with the continuous 6-day coverage of the Antarctic margins by Sentinel-1, the InSAR-based crack delineation
 opens the possibility for operational monitoring of natural or climate change-driven damages and rifting activity over most
 ice shelves, as well as the detection of ongoing breakoff processes and precursor signs of calving events. Thanks to the high
 460 sensitivity of InSAR to dynamic changes in the ice shelf stress field, the rifting activity can be captured well before it is
 visible in SAR backscatter images. With SAR interferometry, the quasi-full propagation of the North Rift could be mapped
 from image pairs acquired about a month before the iceberg broke off. This is a major advantage for predicting future
 calving events and to improve modelling of the response of ice shelves to damages.

Future work should focus on testing the method on other ice shelves, with various structures and geometries, and on
 465 improving the post-processing for reducing the errors in the detected cracks.

Data availability. Sentinel-1 satellite data are freely available on the ESA Open Access Hub (<https://scihub.copernicus.eu>).
 Interferometric products and delineated crack generated in this study can be made available on request.

Author contributions. LL developed the algorithm, performed the processing, led the data analysis and drafted the
 manuscript. JW and TN contributed to the data interpretation and the discussion of the results, and revised the manuscript.
