11

12 **Abstract**

13 The rate of ocean-driven retreat of Greenland's tidewater glaciers remains highly uncertain in  
14 predictions of future sea level rise, in part due to poorly constrained glacier-adjacent water properties.  
15 Icebergs and their meltwater contributions are likely important modifiers of fjord water properties, yet  
16 their effect is poorly understood. Here, we use a 3-D ocean circulation model, coupled to a submarine  
17 iceberg melt module, to investigate the effect of submarine iceberg melting on glacier-adjacent water  
18 properties in a range of idealised settings. Submarine iceberg melting can modify glacier-adjacent water  
19 properties in three principal ways: (1) substantial cooling and modest freshening in the upper ~50 m of  
20 the water column; (2) warming of Polar Water at intermediate depths due to iceberg melt-induced  
21 upwelling of warm Atlantic Water, and; (3) warming of the deeper Atlantic Water layer when vertical  
22 temperature gradients through this layer are steep (due to vertical mixing of warm water at depth), but  
23 cooling of the Atlantic Water layer when vertical temperature gradients are shallow. The overall effect  
24 of iceberg melt is to make glacier-adjacent water properties more uniform with depth. When icebergs  
25 extend to, or below, the depth of a sill at the fjord mouth, they can cause cooling throughout the entire  
26 water column. All of these effects are more pronounced in fjords with higher iceberg concentrations  
27 and deeper iceberg keel depths. These iceberg melt-induced changes to glacier-adjacent water  
28 properties will reduce rates of glacier submarine melting near the surface, but increase them in the Polar  
29 Water layer, and cause typically modest impacts in the Atlantic Water layer. These results characterise  
30 the important role of submarine iceberg melting in modifying ice sheet-ocean interaction, and highlight  
31 the need to improve representations of fjord processes in ice sheet-scale models.

32

## 33 1. Introduction

34 Predicting the rates of ocean-driven retreat of Greenland's tidewater glaciers remains one of the largest  
35 uncertainties in estimating future sea level rise (Edwards et al., 2021; Meredith et al., 2020). This  
36 uncertainty is partly due to limited constraints on the ocean-driven thermal forcing of tidewater glacier  
37 calving fronts, which reflects in part the difficulty in obtaining hydrographic observations in the  
38 proximity of tidewater glacier termini (Jackson et al., 2017, 2020; Sutherland et al., 2019). The few  
39 observations of water properties in the inner part of glacial fjords demonstrate that there are typically  
40 substantial differences between glacier-adjacent water properties and those near the fjord mouth (e.g.  
41 Inall et al., 2014; Jakobsson et al., 2020; Straneo et al., 2011), indicating that substantial modification  
42 of water temperature and salinity can occur within glacial fjords. Due to the relatively small number of  
43 observations and insufficient model constraints on glacier-adjacent water properties, ice sheet models  
44 used to simulate glacier retreat must be forced with far-field (i.e. acquired on and beyond the continental  
45 shelf) ocean boundary conditions that do not include fjord-scale influences (Goelzer et al., 2020; Slater  
46 et al., 2019), thereby introducing uncertainty into the resulting projections of ice sheet mass loss.

47 Glacier-adjacent water properties can differ from those near the fjord mouth for several reasons.  
48 Meltwater runoff enters the fjord at depth where tidewater glaciers meet the ocean ('subglacial  
49 discharge'). In Greenland's fjords, warm water of Atlantic origin (Atlantic Water, AW) is generally  
50 found at depth, whilst colder, fresher water of Polar origin (Polar Water, PW) is found at intermediate  
51 depths (Straneo and Heimbach, 2013; Sutherland and Pickart, 2008). The cold, fresh subglacial  
52 discharge is buoyant when it enters the fjord, so rises as a turbulent plume (Jenkins, 2011). As it rises,  
53 it entrains fjord water, which mixes with the subglacial discharge as it ascends towards the fjord surface  
54 (e.g. Beaird et al., 2018). In this way, subglacial discharge-driven plumes act as mixing engines at the  
55 head of glacial fjords. Due to the temperature stratification in Greenland's fjords, plumes at deeply-  
56 grounded glaciers (i.e. deeper than the PW-AW interface) often draw the relatively warm AW towards  
57 the fjord surface, thereby warming surface and near-surface waters (e.g. Carroll et al., 2016; Straneo et  
58 al., 2010, 2011). In contrast, plumes at shallowly-grounded glaciers can cause cooling at and near the  
59 fjord surface, as cold subglacial discharge and entrained PW is upwelled into surface layers that are  
60 seasonally warmed by solar radiation (Carroll et al., 2016). Models that include glacial plumes are able  
61 to reproduce these effects convincingly (Carroll et al., 2016; Cowton et al., 2015; Jackson et al., 2017).  
62 However, there remain substantial differences between modelled water properties and those that are  
63 observed adjacent to tidewater glaciers (Cowton et al., 2016; Davison et al., 2020; Fraser and Inall,  
64 2018).

65 Several recent studies have identified icebergs as a substantial freshwater source in some of Greenland's  
66 fjords, with iceberg freshwater volumes comparable to or greater than ice sheet runoff (Enderlin et al.,  
67 2016, 2018; Jackson and Straneo, 2016; Moon et al., 2017; Moyer et al., 2019; Rezvanbehbahani et al.,  
68 2020). Furthermore, modelling of one of these fjords suggests that including the heat and salt fluxes

69 associated with submarine iceberg melting increases greatly the model’s ability to reproduce observed  
70 glacier-adjacent water properties (Davison et al., 2020). However, iceberg concentration, keel depth,  
71 and size-frequency distribution likely vary hugely between fjords as well as over time, though  
72 observations of icebergs at the fjord scale are sparse (Enderlin et al., 2016; Moyer et al., 2019;  
73 Rezvanbehbahani et al., 2020; Sulak et al., 2017). As such, it is likely that the effect of icebergs on  
74 glacier-adjacent water properties will also vary both spatially (i.e. between fjords) and temporally. This  
75 variability likely results in different thermal forcing of tidewater glaciers for a given set of far-field  
76 ocean conditions. Constraining the effect of icebergs on glacier-adjacent water properties, and thus  
77 glacier submarine melt rates, is therefore a necessary step in order to improve projections of ice sheet  
78 mass loss.

79 Here, we use an ocean circulation model in a series of idealised fjord-scale simulations to examine how  
80 icebergs affect glacier-adjacent water properties across a range of Greenland-relevant scenarios. We  
81 first consider how iceberg concentration, keel depth and size-frequency distribution individually affect  
82 glacier-adjacent water properties. We then consider a range of representative iceberg and ocean  
83 scenarios, to examine how these parameters interact to determine water properties in the critical region  
84 adjacent to tidewater glacier termini. Greenland’s fjords are complex and varied in their geometry,  
85 ranging from short, narrow inlets to those that are long and wide, each with varying sinuosity and  
86 bathymetry, and often with several tributaries and sills of varying depth along their length. It would be  
87 impractical to attempt to characterise all of these systems. Therefore, we focus here on two simple fjord  
88 geometries: one with no sills and another with a single entrance sill, which we expect to be of particular  
89 importance for iceberg-ocean interaction given the capacity of sills to concentrate fjord-shelf water  
90 exchange near the surface where icebergs are concentrated (Schaffer et al., 2020).

91

## 92 **2. Methods**

### 93 **2.1. Model domain**

94 We use the Massachusetts Institute of Technology general circulation model (MITgcm) in its non-  
95 hydrostatic configuration (Marshall et al., 1997a, 1997b) to model submarine ice melting and circulation  
96 in an idealised fjord 50 km in length and 5 km in width. In most simulations, the domain is uniformly  
97 500 m deep. However, in some simulations, we include a sill which limits the overlying water depth to  
98 100 m (uniform across the entire width of the fjord, and approximately 5 km wide in the along-fjord  
99 direction, with a Gaussian profile), centred 10 km from the open boundary (Fig. 1a). Model resolution  
100 is uniformly 500 m horizontally and 10 m vertically. The fjord sides are closed boundaries, while at the  
101 open ocean boundary we impose a 5 km sponge layer, in which conditions are relaxed towards those  
102 imposed at the boundary (e.g. Cowton et al., 2016; Sciascia et al., 2013; Slater et al., 2015). The glacier-  
103 end of the domain is closed and consists of a virtual ice wall 5 km wide and 500 m high. In simulations

Figure 1. Model domain and boundary conditions. (a) Plan-view of model bathymetry with sill, with the ice wall at the left end of the domain (0 km) and the open boundary on the right. Hatching indicates model resolution (note that grid cells are 500 m x 500 m in the horizontal). The red dot marks the location of subglacial discharge injection and the red box indicates the region from which steady-state glacier-adjacent water properties were extracted. In simulations without a sill, the domain is uniformly 500 m deep. Vertical profiles of (b) temperature, (c) salinity and (d) density with *BCstandard*. (e) Temperature profiles with varying PW temperature. (f) Temperature profiles with varying AW temperature. (g) Example plume vertical velocity from the simulation with iceberg scenario five,  $500 \text{ m}^3 \text{ s}^{-1}$  subglacial discharge and *BCstandard* boundary conditions.

104 incorporating subglacial discharge, this is input at a rate of  $500 \text{ m}^3 \text{ s}^{-1}$ , a value typical of many of  
 105 Greenland's tidewater glaciers (Mankoff et al., 2020), at the centre of the base of the ice wall (Fig. 1a).  
 106 The velocity of the subglacial discharge-driven plume (e.g. Fig. 1g) and the melting of the ice wall were  
 107 calculated using the 'IcePlume' package (Cowton et al., 2015). In common with several previous studies  
 108 (Kimura et al., 2014; Slater et al., 2015; Xu et al., 2013), we implement a free slip condition on the fjord  
 109 walls and ice front and do not simulate the effects of sea ice, atmospheric forcing or tides.

## 110 2.2. Initial and open boundary conditions

111 We use idealised representations of temperature and salinity profiles commonly observed at the mouth  
 112 of Greenland's south-eastern fjords during late-summer as initial and open boundary conditions  
 113 (Sutherland et al., 2014). In our standard setup, this idealised profile is a cubic interpolation between  
 114  $6^\circ\text{C}$  and 31 psu at the fjord surface,  $0^\circ\text{C}$  and 34 psu at 100 m depth,  $2^\circ\text{C}$  at 200 m and  $3.5^\circ\text{C}$  at 500 m  
 115 depth, where salinity is greatest at 35 psu (Fig. 1b-d). In this way, the upper several tens of metres  
 116 represent waters that are seasonally warmed by solar insolation, whilst the relatively cold intermediate

117 layer, centred 100 m below the fjord surface, represents the PW layer, which is underlain by warmer,  
118 more saline water representing the AW layer. Henceforth, we refer to this set of boundary conditions  
119 as *BCstandard*. In separate simulations, we use temperature minima at 100 m of  $-1^{\circ}\text{C}$  (*PWcool*) and  
120  $1^{\circ}\text{C}$  (*PWwarm*) and temperature maxima at 500 m of  $2.5^{\circ}\text{C}$  (*AWcool*) and  $4.5^{\circ}\text{C}$  (*AWwarm*) (Fig. 1e,f).  
121 Changing the temperature of the AW and PW layers causes corresponding changes in the vertical  
122 temperature gradient (Fig. 1e,f), the effects of which are discussed in Sect. 3.2. Initial and open  
123 boundary salinity are kept constant between simulations, but density changes between simulations are  
124 negligible. Boundary conditions were kept constant throughout each simulation. We focus on late-  
125 summer ocean conditions because of the greater availability of observations at that time to both force  
126 the model and with which to make comparisons.

127

### 128 **2.3. Iceberg-ocean interaction**

129 Submarine iceberg melting is simulated using the ‘IceBerg’ package within MITgcm (Davison et al.,  
130 2020), with an ice temperature of  $-10^{\circ}\text{C}$  (Inall et al., 2014; Luthi et al., 2002; Sciascia et al., 2013;  
131 Sutherland and Straneo, 2012). This package uses the velocity-dependent three-equation melt rate  
132 parameterisation (Hellmer and Olbers, 1989; Holland and Jenkins, 1999; Xu et al., 2012). We chose to  
133 use this melt rate parameterisation, rather than existing iceberg melt parameterisations (e.g. Bigg et al.,  
134 1997), because it enables us to resolve the vertical pattern of submarine melting of individual icebergs.  
135 The temperature and salinity fluxes associated with melting of individual iceberg faces within a grid  
136 cell are calculated based on local temperature, salinity and face-normal velocity. Face-normal current  
137 speed is calculated assuming that icebergs drift with the average current velocity along their draught  
138 (though we note that the iceberg locations are kept constant through each simulation). Melt-driven  
139 plumes are not simulated directly; instead, their effect on melt rates is parameterised by applying a  
140 minimum face-normal current speed of  $0.06\text{ m s}^{-1}$  to each iceberg face. This minimum current speed is  
141 based on line plume modelling (Davison et al., 2020). The package does not include the effect of waves  
142 or mechanical iceberg breakup; therefore, melt rates calculated here are conservative. We use standard  
143 parameter values (Cowton et al., 2015; Davison et al., 2020; Jackson et al., 2020) for the drag coefficient  
144 (0.0025), and thermal and salt turbulent transfer coefficients (0.022 and 0.00062, respectively). The  
145 icebergs are rectangular in plan-view and have flat, vertical sides. All icebergs have length,  $l$ , to width  
146 ratios of 1.62:1 (Dowdeswell et al., 1992), and iceberg keel depth,  $d$ , is related to iceberg length through,  
147  $d=2.91l^{0.71}$  (Barker et al., 2004).

148 In Sect. 3.1, we consider a range of iceberg concentrations, maximum keel depths and size-frequency  
149 distributions, whilst using only the *BCstandard* boundary conditions. In all setups, iceberg  
150 concentration is uniform across the fjord and decreases linearly from a maximum adjacent to the virtual  
151 ice wall to a minimum 10 km from the open boundary. In Sect. 3.1, iceberg concentration (defined as

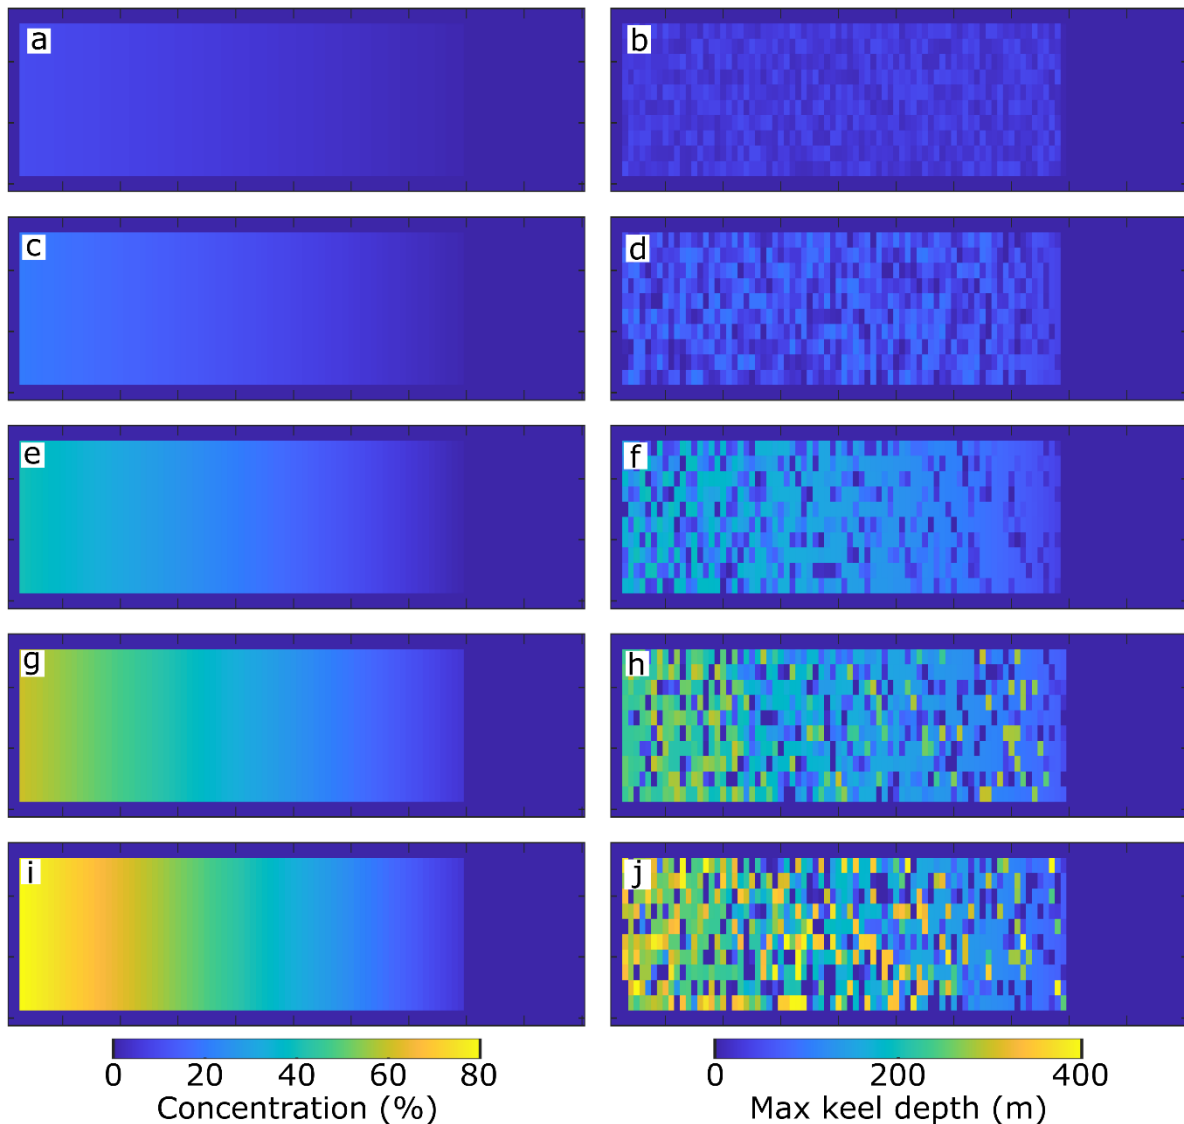

Figure 2. Iceberg concentration (left column) and maximum iceberg keel depth (right column) for iceberg scenarios one to five (top to bottom). All panels show the domain in plan-view, and are 50 km long and 5 km across.

152 the percentage of the fjord surface in plan-view occupied by icebergs), is 80% adjacent to the ice wall  
 153 and decreases to 5% in our  $c1$  experiment, and is reduced to 75, 50 and 25% of these values in our  
 154  $c0.75$ ,  $c0.5$ , and  $c0.25$  experiments, respectively. Regardless of concentration, we use a maximum  
 155 iceberg keel depth of 300 m and the size-frequency distribution of the icebergs is described using a  
 156 power law with an exponent of -2, which is similar to that observed in Sermilik Fjord (Sulak et al.,  
 157 2017). In separate simulations, we assign maximum iceberg keel depths of 50 m, 150 m, 250 m, 350 m  
 158 and 450 m, whilst maintaining the  $c1$  concentration and the -2 power law exponent. We then vary the  
 159 size-frequency distribution power law exponent from -1.6 to -2.1 in increments of 0.1 (covering the  
 160 range observed to date in Greenland's fjords (Rezvanbehbahani et al., 2020; Sulak et al., 2017)), whilst

Table 1. Details of each iceberg scenario. Concentration is the percentage of the fjord in plan-view occupied by icebergs. Iceberg concentration was linearly interpolated from the maximum value (adjacent to the glacier wall) to the minimum value 40 km down fjord.

<b>Iceberg scenario</b>	<b>Max. draught (m)</b>	<b>Exponent</b>	<b>Concentration [max,min] (%)</b>	<b>Surface area (km<sup>2</sup>)</b>
Scenario 1	50	1.6	[10,1]	44.5
Scenario 2	100	1.7	[20,1]	76.5
Scenario 3	200	1.8	[40,1]	141
Scenario 4	300	1.9	[60,5]	235
Scenario 5	400	2.1	[80,5]	316

161 retaining the  $cI$  concentration and the 300 m maximum keel depth. In this section (Sect. 3.1) we show  
 162 results from simulations both with and without subglacial discharge, to demonstrate the effect of  
 163 icebergs in isolation and in combination with subglacial discharge.

164 In Sect. 3.2 onwards, we consider five realistic combinations of iceberg concentration, maximum  
 165 iceberg keel depth and power law exponent, in order to approximate the range of iceberg geometries  
 166 and distributions found in Greenland’s fjords in summer (Fig. 2). In these setups, iceberg concentration  
 167 decreases linearly in the along-fjord direction away from the glacier between specified maximum and  
 168 minimum values (Table 1) and icebergs are distributed randomly in the across-fjord direction (Fig. 2).  
 169 These iceberg setups range from those representing a fjord hosting few and small icebergs, such as  
 170 Kangerlussuup Sermia Fjord (Sulak et al., 2017) (scenario one), to those representing an iceberg-  
 171 congested fjord, such as Sermilik Fjord (scenario five) (Fig. 2; Table 1). In all simulations shown in this  
 172 section (Sect. 3.2)  $500 \text{ m}^3 \text{ s}^{-1}$  subglacial discharge is injected into the fjord as described in Section 2.1.

173

### 174 **3. Results**

#### 175 **3.1. The effect of iceberg concentration, keel depth and size-frequency distribution on glacier- 176 adjacent water properties**

177 The effect of iceberg melt on glacier-adjacent water properties depends on iceberg geometry, iceberg  
 178 concentration and iceberg size-frequency distribution (Fig. 3), as well as on the presence or absence of  
 179 subglacial discharge. In the absence of subglacial discharge, icebergs modify glacier-adjacent water  
 180 properties (here defined as the average properties of the water within 2 km of the ice wall; Fig. 1a) in  
 181 two main ways. Firstly, they cause substantial ( $6\text{-}7.5^\circ\text{C}$ ) cooling in the upper  $\sim 60$  m of the water column,  
 182 relative to the initial conditions (Fig. 3a-c). The amount of cooling in this near-surface layer depends  
 183 somewhat on iceberg concentration, with steady-state water temperature varying between  $\sim -1.5^\circ\text{C}$  and  
 184  $\sim 0^\circ\text{C}$  over the range of iceberg concentrations considered, but is otherwise relatively insensitive to  
 185 changing iceberg geometry and distribution (Fig. 3a-c). Secondly, warming of up to  $\sim 1^\circ\text{C}$  occurs below  
 186  $\sim 80$  m because iceberg melting causes localised freshening at depth. The resulting iceberg melt-

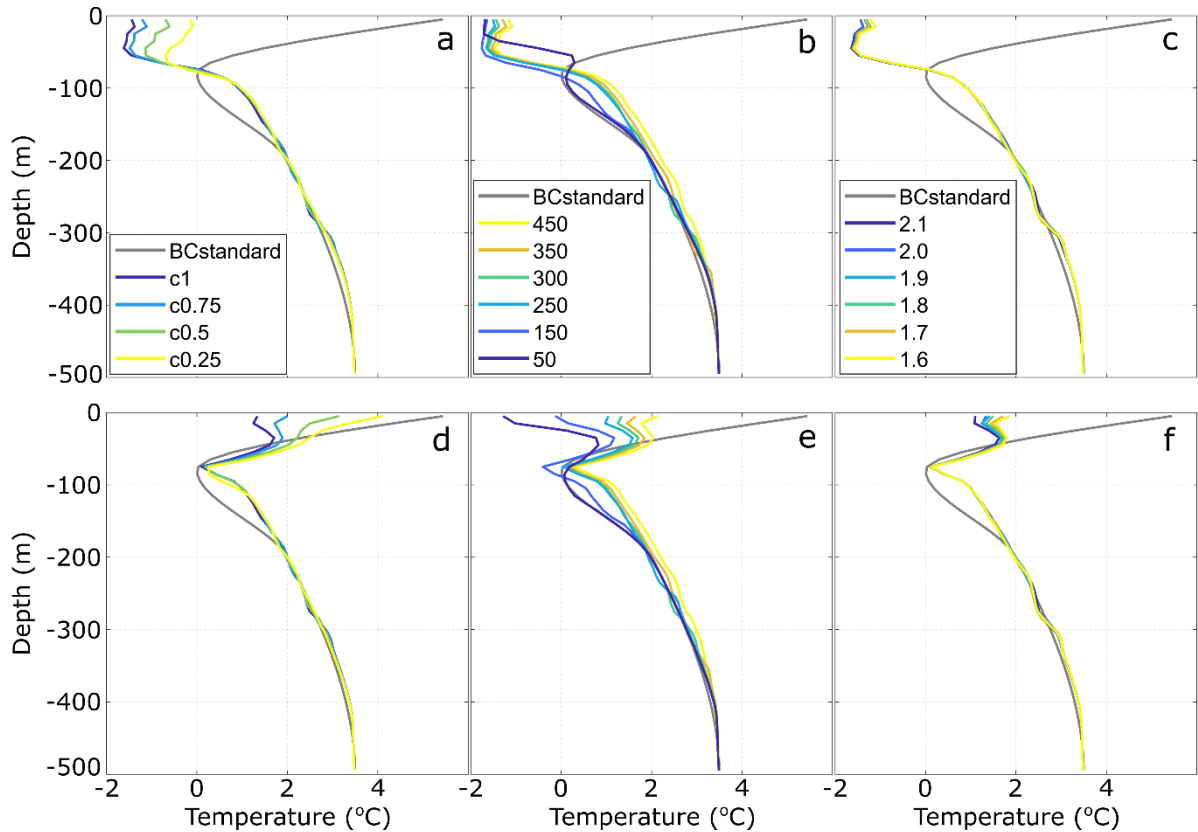

Figure 3. Glacier-adjacent water temperature vs iceberg geometry and distribution. Effect of iceberg concentration (a & d), maximum iceberg draught (b & e) and exponent describing the size-frequency distribution (c & f). Panels (a-c) are for simulations without subglacial discharge, whilst panels (d-f) are for simulations with  $500 \text{ m}^3 \text{ s}^{-1}$  subglacial discharge.

187 modified water (i.e. the mixture of iceberg freshwater and ambient water at depth) is less dense than the  
 188 surrounding water and rises buoyantly towards the fjord surface. The vertical extent and magnitude of  
 189 the resulting warming generally increase with maximum iceberg keel depth (Fig. 3b), because icebergs  
 190 with deeper keels cause upwelling of deeper AW (which in this case is also warmer (Fig. 1b)). This  
 191 warming effect does not extend to the fjord surface, because the stronger stratification near the surface  
 192 limits upwelling and because iceberg-ocean contact areas are much greater near the surface, so cooling  
 193 due to localised iceberg melting dominates. When subglacial discharge is included, the effect of iceberg  
 194 melt on glacier-adjacent water properties at depth (below 60 m) is similar to that in simulations without  
 195 subglacial discharge, but glacier-adjacent water temperatures in the upper  $\sim 60$  m of the water column  
 196 display a greater range and the cooling of the near-surface waters is considerably reduced (Fig. 3d-f).  
 197 This is because the subglacial discharge causes strong upwelling of AW towards the fjord surface and  
 198 increases rates of fjord-shelf exchange, which counters some of the iceberg-induced cooling of near-  
 199 surface waters.

200

### 201 **3.2. Combining iceberg scenarios and ocean conditions**

202 In reality, changes in iceberg concentration, keel depth and size-frequency distribution do not occur in  
203 isolation and there are characteristic relationships between those iceberg descriptors (Sulak et al., 2017).  
204 Fjords hosting large glaciers, such as Sermilik Fjord and Helheim Glacier in east Greenland, tend to  
205 contain both high iceberg concentrations and large, deeply-draughted icebergs, whilst those with lower  
206 iceberg concentrations, such as Kangerlussuup Sermia Fjord, also tend to contain smaller icebergs. To  
207 better represent the range of iceberg conditions found in Greenland's fjords, we consider five iceberg  
208 'scenarios' (Fig. 2; Table 1), ranging from a fjord with low iceberg concentration, shallow iceberg keels  
209 and fairly uniform iceberg sizes (iceberg scenario one), to a fjord with high iceberg concentration, deep  
210 iceberg keels and a large range of iceberg sizes (iceberg scenario five). For each of these scenarios, we  
211 examine steady-state glacier-adjacent water temperature for a range of ocean boundary conditions, and  
212 with and without a shallow (100 m) sill. We therefore consider three different PW and AW temperatures  
213 in turn (Fig. 1e,f), and examine the resulting glacier-adjacent water properties for each of the five  
214 iceberg scenarios. To isolate the effect of iceberg melting from other processes, we compare each of the  
215 above simulations to identical simulations without icebergs.

216

#### 217 **3.2.1. Changing Polar Water temperature**

218 Fig. 4 shows steady-state glacier-adjacent water properties for the range of iceberg scenarios and PW  
219 temperatures considered. In all iceberg scenarios, there is substantial ( $\sim 2^\circ\text{C}$  or more) cooling in the  
220 upper  $\sim 60$  m, with greater cooling in scenarios with higher iceberg concentrations. Other than this near-  
221 surface cooling, glacier-adjacent water properties are very similar to open ocean conditions in iceberg  
222 scenarios one and two (which have the lowest iceberg concentrations; Fig. 2; Table 1). However, in  
223 iceberg scenarios three to five, the PW layer is increasingly modified (Fig.s 4c-e). With *PWcool*,  
224 icebergs in these scenarios cause on average a net *warming* of  $1.02^\circ\text{C}$  in the 80-200 m depth range,  
225 compared to simulations without icebergs. Conversely, with *PWwarm*, the icebergs cause a net cooling  
226 of  $0.30^\circ\text{C}$  over the same depth range, such that the steady-state temperature profiles for both sets of  
227 initial conditions (*PWcool* and *PWwarm*) are similar. With *BCstandard*, the influence of icebergs on  
228 glacier-adjacent water properties falls between the two, with the net effect being a slight ( $0.43^\circ\text{C}$ )  
229 warming (Fig. 4c-e). These changes arise due to differing balances between cooling due to iceberg  
230 melting, and warming due to buoyancy-induced upwelling of relatively warm AW water. With *PWcool*  
231 there is relatively little iceberg melting in the PW layer (because the PW is close to the *in-situ* freezing  
232 point), and so warming due to upwelling of AW dominates (driven by iceberg melting at greater depth  
233 in the warmer AW layer). In contrast, with *PWwarm*, iceberg melt rates in the PW layer are  
234 comparatively high, and the temperature difference between the PW and AW layers is reduced, so  
235 localised cooling offsets warming due to turbulent upwelling. In short, under the conditions represented

Figure 4. Steady-state glacier-adjacent water temperature for a range of initial Polar Water conditions. In all plots, solid and dashed lines indicate simulations with and without icebergs, respectively. Plots a-e show configurations with a flat-bottomed domain, whilst f-j show those with a 100 m deep sill. Grey, blue and red lines show scenarios using the *BCstandard*, *PWcool* and *PWwarm* boundary conditions respectively (shown in Figure 1e). The horizontal grey lines indicate the maximum iceberg keel depth in each scenario, and the horizontal orange lines in panels f-j indicate the sill depth.

236 by these simulations, submarine iceberg melting acts to make glacier-adjacent water temperature more  
 237 uniform with depth (Fig. 4c-e).

238 The addition of a 100 m deep sill near the fjord mouth serves to amplify the cooling effect of icebergs  
 239 (Fig. 4f-j). Sills typically block external shelf waters below the sill depth from entering the fjord (unless  
 240 external forcing causes a shallowing of isopycnals seaward of the sill), causing the fjord basin bounded  
 241 by the sill to be replenished by waters sourced only from above the sill depth (e.g. Jakobsson et al.,  
 242 2020). When icebergs reach down to the sill depth, all water entering the fjord may thus be subject to  
 243 melt-driven cooling. The result is that icebergs cause cooling throughout the water column, even below  
 244 the deepest iceberg keels and below the sill depth (Fig. 4f-j). This cooling is increasingly pronounced  
 245 as the PW temperature increases and with more concentrated and deeper icebergs (Fig. 4f-j). For  
 246 example, over the 100 to 500 m depth range with *PWcool*, icebergs cause 0.21°C cooling on average in  
 247 iceberg scenarios three to five (0.06°C in scenario three and 0.35°C in scenario five); whilst with  
 248 *PWwarm*, icebergs cause 0.67°C cooling on average (0.33°C in scenario three and 0.91°C in scenario  
 249 five).

250 The varied effects of icebergs on glacier-adjacent water properties are apparent in temperature-salinity  
 251 space (Fig. 5). Initial glacier-adjacent water properties are inherited from those prescribed at the fjord  
 252 mouth; however, icebergs modify fjord waters through ice melt and meltwater-driven vertical mixing.

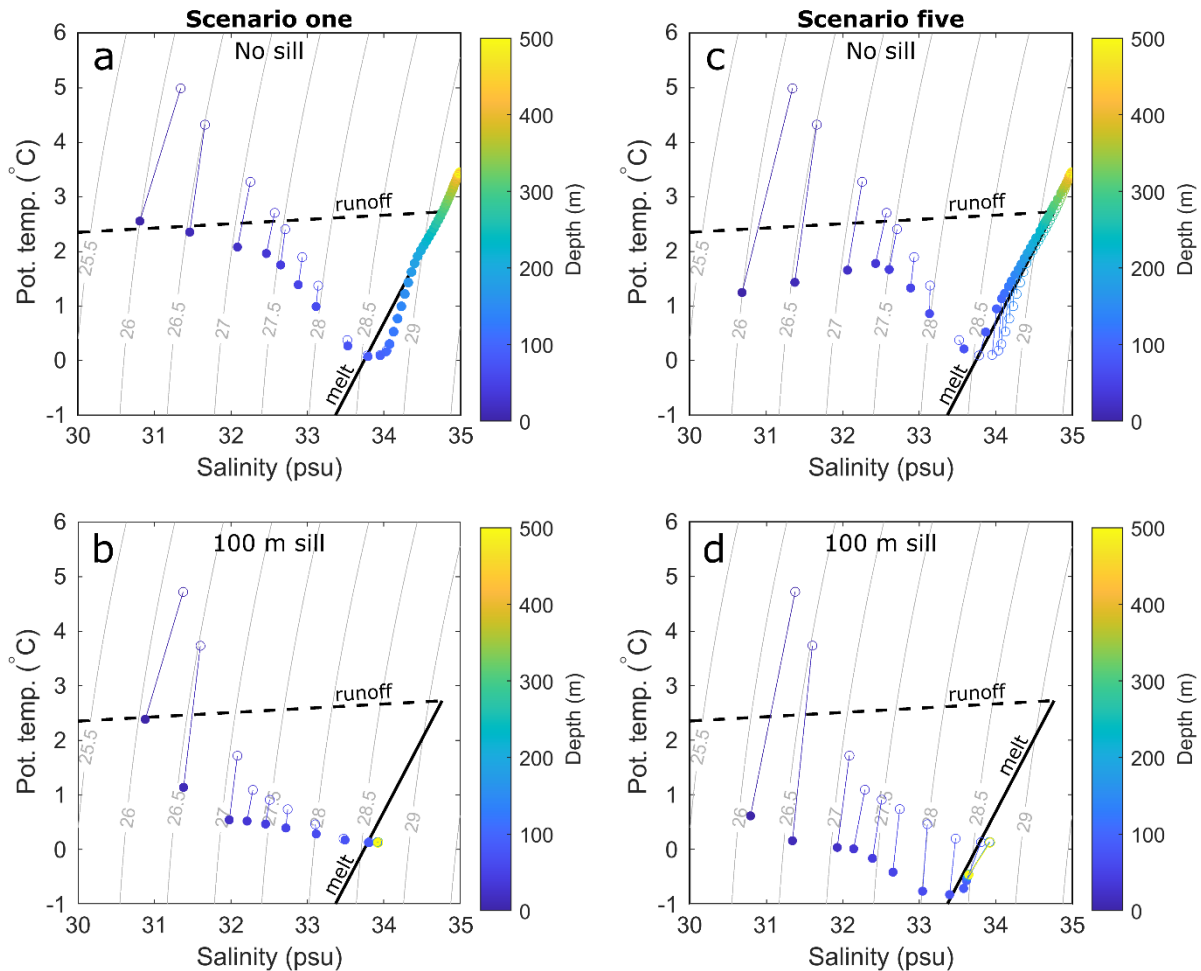

Figure 5. Glacier-adjacent temperature and salinity with (solid circles) and without icebergs (open circles) for various iceberg and sill scenarios and with *BCstandard* boundary conditions. Panels (a) and (b) show iceberg scenario one without a 100 m sill (a) and with a sill (b). Panels (c) and (d) show iceberg scenario five, without a sill (c) and with a 100 m sill (d). Solid lines joining open and closed circles indicate connected data points extracted from the same model depth.

253 Comparing temperature-salinity profiles of simulations with and without icebergs illustrates these  
 254 effects (Fig. 5). In the upper ~60 m of all simulations with icebergs, iceberg melting causes substantial  
 255 cooling and slight freshening (e.g. compare solid and open circles in Fig. 5 – solid circles are drawn  
 256 down and slightly left in temperature-salinity space). Deeper in the water column (below 100 m), the  
 257 influence of iceberg melting on water properties depends on the iceberg scenario and the presence or  
 258 absence of a sill. In iceberg scenario one (Fig. 5a, b), iceberg melting causes very little modification of  
 259 waters below 100 m, even in the presence of a sill (Fig. 5b). This is because the icebergs do not extend  
 260 to the sill water depth and so there is some unmodified exchange between the fjord and shelf. In iceberg  
 261 scenario five, icebergs cause on average 0.19°C warming of waters below 100 m when there is no sill,  
 262 and cooling of 0.61°C below 100 m when there is a sill (Fig. 5b). This cooling below the maximum  
 263 iceberg draught occurs in all iceberg scenarios in which icebergs extend to sill depth, but is most  
 264 apparent in the higher iceberg concentration scenarios (e.g. Fig. 5d). The simulated changes in water

265 properties arise due the combined effects of local iceberg melting and fjord circulation. Submarine  
266 iceberg melting reduces the density of surrounding waters, causing upwelling until those waters  
267 equilibrate at a new neutral buoyancy depth with respect to the fjord stratification. Within the  
268 temperature-salinity space of Greenland's fjords, density is predominantly salinity controlled.  
269 Therefore, the salinity stratification is little changed by iceberg melting, whilst the temperature changes  
270 are much more pronounced. This means that the iceberg melt-induced migrations through temperature-  
271 salinity space that are often steeper than predicted by the submarine melt mixing line (Gade, 1979).

272

### 273 **3.2.2. Changing Atlantic Water temperature**

274 We also examine the interactions between iceberg scenarios and changes to AW temperature (Fig. 6).  
275 As in the PW scenarios, there is always marked cooling in the upper ~60 m of the water column and  
276 water modification below this is minimal for iceberg scenarios one and two. In iceberg scenarios three  
277 to five, icebergs penetrate to a greater depth and thus into the AW layer, releasing freshwater which  
278 causes upwelling of AW. In these cases, the net effect of icebergs on water properties between ~80 m  
279 and the maximum iceberg keel depth depends on the balance between cooling due to localised iceberg  
280 melting, and warming due to upwelling of AW. With *AWwarm*, there is a steep temperature gradient  
281 between the cold PW and warmer AW layers. Consequently, upwelling of AW causes notable warming  
282 in the PW layer that offsets localised iceberg-induced cooling. In the scenarios with greater iceberg  
283 concentration (e.g. iceberg scenario five; Fig. 6e), the icebergs penetrate deeper into the AW layer and  
284 so can induce upwelling of the deeper, warmer water, resulting in more warming and over a greater  
285 depth range than in the lower iceberg concentration scenarios. However, with *AWcool*, the vertical  
286 temperature gradient is reduced, so cooling due to localised iceberg melting dominates the signal  
287 between the maximum iceberg draught and ~80 m.

288 This dependence of iceberg modification of glacier-adjacent water properties on the temperature  
289 gradient through the AW layer is further illustrated by sensitivity tests in which the temperature of the  
290 AW layer was modified in two ways relative to *BCstandard*. First, to examine whether the absolute  
291 temperature of the water column affected the balance between upwelling and melting, the entire water  
292 column was uniformly warmed by 1°C. With this uniform shift in temperature, the pattern of  
293 temperature with depth is similar to that of *BCstandard* (compare dashed grey and red lines in Fig. 7b),  
294 illustrating that the additional upwelling-driven warming with *AWwarm* is due to the steeper  
295 temperature gradient between the PW and AW layers, rather than the absolute temperature of the AW.  
296 Secondly, to illustrate the importance of the temperature gradient within the AW layer, we made the  
297 AW layer uniformly 3.5°C. With this set of boundary conditions, upwelling-driven warming dominates  
298 in the PW layer, because of upwelling of warm AW, whilst melt-driven cooling dominates in the AW  
299 layer because upwelling-driven warming is muted (Fig. 7c). Thus, the average warming below ~80 m

Figure 6. Steady-state glacier-adjacent water temperature for a range of initial Atlantic Water conditions and with a flat-bottomed domain. In all plots, solid and dashed lines indicate simulations with and without icebergs, respectively. Grey, blue and red lines show scenarios using the *BCstandard*, *AWcool* and *AWwarm* boundary conditions, respectively (shown in Figure 1f). The horizontal grey lines indicate the maximum iceberg keel depth in each scenario.

300 that we simulate with *AWwarm* is strongly sensitive to the vertical temperature gradient, and not only  
 301 the average or maximum temperature of the AW.

302 With the addition of a 100 m sill, AW does not propagate into the fjord under the conditions simulated  
 303 here. Thus in steady-state, glacier-adjacent water properties are unaffected by AW and adopt the  
 304 properties of the PW layer (modified by iceberg melting and subglacial discharge). The resulting  
 305 profiles therefore resemble the dashed pale blue lines in Fig. 4f-j and are not shown here.

306

## 307 4. Discussion

### 308 4.1. Comparison with observations and applicability to real fjords

309 Our simulations suggest that several changes to glacier-adjacent water properties can occur due to  
 310 submarine iceberg melting. In almost all simulations, we simulate pronounced ( $>2^{\circ}\text{C}$ ) cooling in the  
 311 upper several tens of metres of the water column. Deeper in the water column (between  $\sim 80$  m and the  
 312 maximum iceberg keel depth), both iceberg-induced cooling and warming can occur (e.g. Fig. 4 and 6),  
 313 depending on the balance between cooling due local iceberg melting and warming due to melt-driven  
 314 upwelling. The balance between these processes depends on the iceberg contact area at depth available  
 315 for local melting (and therefore cooling) and on the temperature of the upwelling water. When vertical  
 316 temperature gradients are steep (e.g. with *AWwarm*; Fig. 6), icebergs can cause warming between their  
 317 maximum keel depth and the surface layer. This is particularly apparent in the PW layer, where the  
 318 temperature difference between an upwelled parcel of water and that at the parcel's new neutral  
 319 buoyancy depth in the PW layer is greatest, and where iceberg melt rates (and therefore melt-driven  
 320 cooling) are generally smaller because of the low water temperatures. In contrast, when vertical  
 321 temperature gradients are shallower (e.g. with *AWcool*), cooling due to localised melting dominates  
 322 (blue lines in Fig. 6d,e and 7c). These effects tend to reduce vertical temperature variations of glacier-

Figure 7. AW temperature gradient sensitivity tests. Panels show simulations using (a) *BCstandard*, (b) temperature profile shifted by 1°C throughout the water column, and (c) uniform initial AW temperature of 3.5°C. Steady-state conditions without icebergs using *BCstandard* (grey line) are also shown in (b) and (c) for reference.

323 adjacent waters compared both to simulations without icebergs and compared to conditions at the fjord  
 324 mouth.

325 Detailed near-glacier hydrographic observations against which to make comparisons are sparse, but  
 326 those that do exist provide some useful insight into the applicability of our model results to Greenland's  
 327 fjords. The pronounced surface and near-surface cooling (relative to conditions at the mouth) that we  
 328 simulate is a common feature in Greenland's fjords. For example, a transect of conductivity,  
 329 temperature, depth (CTD) casts along Sermilik Fjord revealed cooling of approximately 4°C in the  
 330 upper ~50 m (Straneo et al., 2011, 2012), which was also reproduced in a detailed modelling study of  
 331 Sermilik Fjord that included icebergs (Davison et al., 2020). Similar along-fjord near-surface cooling  
 332 has also been observed in other iceberg-congested fjords, such as Illulissat Isfjord (Beaird et al., 2017;  
 333 Gladish et al., 2015) and Upernavik Isfjord (Fenty et al., 2016), both in west Greenland. In Illulissat  
 334 Isfjord, the cold surface layer usually extends along-fjord to a shallow sill at the fjord mouth, where  
 335 icebergs frequently become grounded (Gladish et al., 2015).

336 Iceberg-induced changes to water properties below ~80 m are harder to identify in hydrographic  
 337 observations, most likely because they also contain the signature of glacial-plumes resulting from  
 338 subglacial discharge, or other external forcings. Our modelling suggests that, if vertical temperature  
 339 gradients are shallow, then icebergs can cause cooling over large depth ranges (e.g. Fig. 7c). As one  
 340 example, hydrographic observations in Kangerdlugssuaq Fjord showed relatively uniform near-glacier  
 341 temperatures with substantial cooling in both the upper 100 m and between 300 and 400 m depth,  
 342 relative to a transect acquired at the fjord mouth (Straneo et al., 2012), consistent with the modelling  
 343 results presented here. Iceberg melt-induced warming of parts of the water column is harder still to

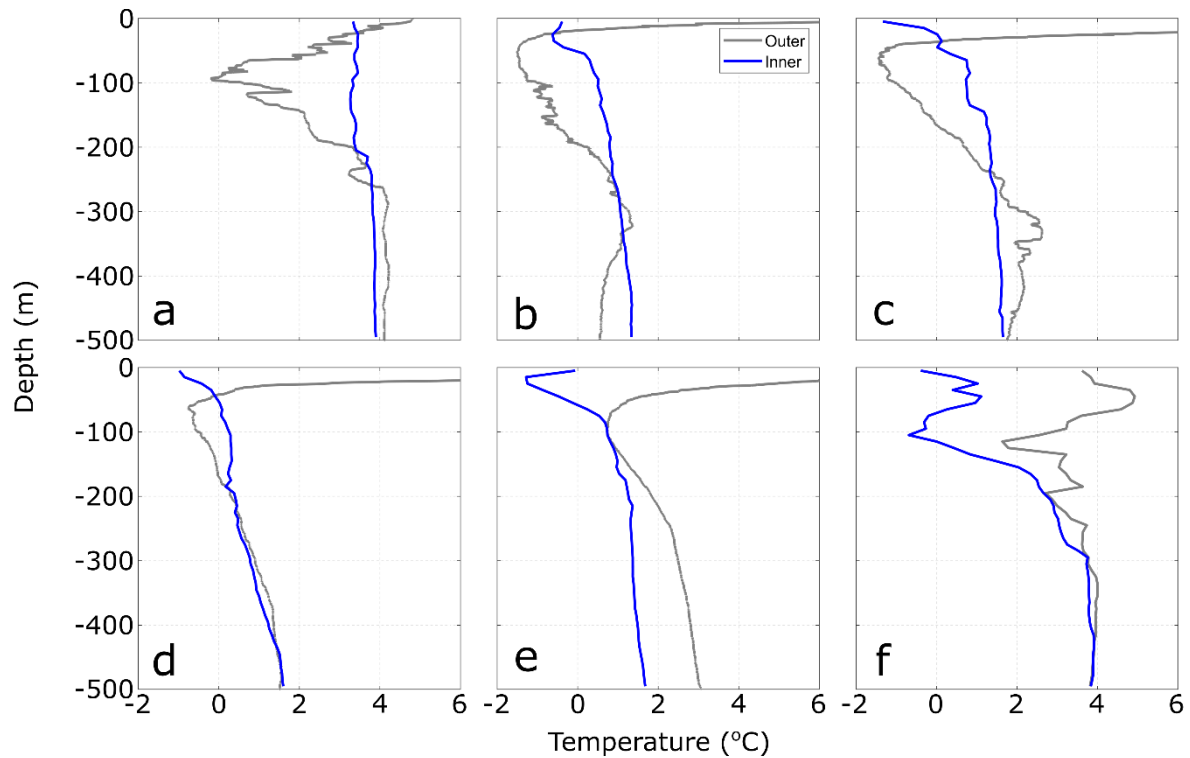

Figure 8. Fjord temperature profiles from the Oceans Melting Greenland project (<https://omg.jpl.nasa.gov/>). The blue lines are profiles acquired within the fjord, close to tidewater glacier termini, and the grey lines are acquired at or beyond the fjord mouth. Fjords (or nearest glacier) shown are (a) Sermilik Fjord, (b) Daugaard-Jensen, (c) Upernavik Isstrom, (d) Nunatakassaap Sermia Fjord, (e) Ilulissat Isfjord, and (f) Timmiarmiut Fjord. Data are available from: <https://omg.jpl.nasa.gov/portal/browse/OMGEV-AXCTD/>

344 identify in published hydrographic observations because of the difficulty in distinguishing it from  
 345 relatively warm subglacial discharge-driven plume outflow.

346 To further compare our modelling results to observations, we examined CTD casts acquired as part of  
 347 the Oceans Melting Greenland (OMG) project (<https://omg.jpl.nasa.gov/>; data available at:  
 348 <https://omg.jpl.nasa.gov/portal/browse/OMGEV-AXCTD/>). In keeping with our simulation design, we  
 349 selected pairs of CTD casts acquired less than a week apart, one near or outside the fjord mouth and the  
 350 other as close as possible to the tidewater glacier at the head of the fjord. These profiles (Fig. 8) show  
 351 many of the characteristics that we have simulated here. Specifically, the profiles show that near-surface  
 352 water temperatures are substantially colder adjacent to tidewater glaciers compared to those observed  
 353 outside each fjord, and the observed temperature differences between the mouth and near-glacier region  
 354 are comparable to those simulated here. In all but two of the surveyed fjords (Ilulissat Isfjord and  
 355 Timmiarmiut Fjord, shown in Figs. 8e & f), the profiles also show warming at intermediate depths (~50-  
 356 200 m) relative to the waters outside the fjord, consistent with our simulations using icebergs scenarios  
 357 three to five, particularly using our *AWwarm* boundary conditions (Figs. 6c-e). These observations do  
 358 not allow us to quantify the relative contributions to intermediate depth warming between plume

359 outflow and iceberg melt-induced upwelling. However, we note that the vertical pattern and magnitudes  
360 of intermediate depth warming are similar to those simulated here. In addition, the intermediate depth  
361 warming occurs over a large depth range, which is not easily explained by plume outflow and is  
362 consistent with our simulations. Some of the profiles also show notable cooling at depth (e.g. Illulissat  
363 Isfjord, Fig. 8e), which we are only able to reproduce in simulations including a shallow sill (e.g. the  
364 red line in Fig. 4j). Our simulations may underestimate cooling at depth because power law size-  
365 frequency distributions underestimate the number of very large icebergs (Sulak et al., 2017) and because  
366 the parameter values used in our melt calculation may underestimate submarine melt rates (Jackson et  
367 al., 2020).

368 In our simulations, we have generally considered a glacier-fjord system in which the glacier face and  
369 subglacial discharge interact with the entire water column, and with icebergs affecting a range of depths  
370 between the surface and their keels, which is a coarse representation of many fjords in Greenland. In  
371 many other fjords in Greenland, glacier grounding lines are shallower, such that the calving front and  
372 subglacial discharge interact predominately with the surface and PW layers. Although our simulations  
373 do not encompass this geometry, they still provide some insights into the potential effect of icebergs on  
374 near-glacier conditions in these fjords. With this geometry, subglacial discharge is injected directly into  
375 the PW layer. Therefore, plume outflow is relatively cool and we would expect, based the simulations  
376 presented here, that iceberg-driven cooling of the surface layer to be significant (resembling Fig. 3a-c).  
377 In addition, icebergs calved from such shallow glaciers would not be able to cause upwelling of warm  
378 AW (as in our scenarios 1 and 2), and so we would not expect any iceberg melt-driven warming of the  
379 PW layer. Overall, we expect, based on the insights gained from our simulations, that the effect of  
380 iceberg melt on near-glacier water properties in shallow fjords therefore largely manifests as a cooling  
381 in the upper several tens of meters of the water column, thereby reducing vertical variations in water  
382 column temperature. Such patterns have been observed in fjords hosting glaciers with relatively shallow  
383 (~250 m) grounding lines resting in the PW layer (e.g. Mortensen et al., 2020).

384

#### 385 **4.2. Implications for glacier-ocean interaction**

386 If iceberg-induced changes to glacier-adjacent water properties significantly affect the magnitude  
387 and/or the vertical pattern of glacier submarine melting, then icebergs may play an important role in  
388 modifying glacier response to ocean forcing. To assess the effect of icebergs on glacier submarine  
389 melting, we first consider how iceberg melt impacts subglacial discharge-driven plume dynamics and  
390 then assess how the simulated temperature changes could affect melt rates across the parts of glacier  
391 fronts that are not directly affected by subglacial discharge-driven plumes.

392 To examine the effect of icebergs on subglacial discharge plume-driven glacier submarine melting, we  
393 evaluate plume properties for a single set of ocean boundary conditions (*BCstandard*; Fig. 1b-d) using

Figure 9. Plume dynamics for iceberg scenarios one to five. (a) Plume vertical velocity. (b) Plume temperature. (c) Glacier submarine melt rate in the plume. All simulations are based on *BCstandard* boundary conditions and  $500 \text{ m s}^{-1}$  subglacial discharge.

394 each of the five iceberg scenarios. We find that submarine iceberg melting has negligible influence on  
 395 plume vertical velocity and only modest influence on plume temperature, meaning plume-induced  
 396 glacier submarine melt rates appear relatively insensitive to the changes in temperature and salinity  
 397 induced by changes in iceberg geometry, concentration and size-frequency distribution (Fig. 9).

398 Although subglacial discharge-driven plume dynamics appear to be relatively insensitive to iceberg-  
 399 induced modification of glacier-adjacent water properties, submarine melting distal to glacial plumes  
 400 (‘background melting’ (e.g. Slater et al., 2018)) may be more directly affected. Qualitatively, the iceberg  
 401 melt-induced changes to glacier-adjacent water properties presented above suggest that iceberg melt  
 402 will affect background glacier melt rates in three key ways: (1) at and near the fjord surface, cooling  
 403 will reduce background melt rates; (2) in the PW layer, background melting will usually increase due  
 404 to upwelling of warmer AW, and; (3) in the AW layer, iceberg melt-induced changes in background  
 405 melt rates are expected to be modest, with slight increases in fjords with steep vertical temperature  
 406 gradients, and slight decreases in other fjords (assuming icebergs penetrate into the AW layer). These  
 407 effects will be more pronounced in fjords with higher concentrations of larger (and thus deeper keeled)  
 408 icebergs. In some fjords, then, where icebergs cause cooling near the surface and warming at depth, we  
 409 expect icebergs will increase glacier undercutting through impacting submarine melt rates, which may  
 410 in turn influence the rate and mechanism of calving (Benn et al., 2017; James et al., 2014; O’Leary and  
 411 Christoffersen, 2013).

412 To explore these effects quantitatively, we calculate the percentage change in background melt rate of  
 413 the glacier terminus due to iceberg-induced modification of glacier-adjacent water temperature (relative  
 414 to simulations without icebergs). Modelling studies indicate that background melt rates scale linearly  
 415 with ocean temperature (Sciascia et al., 2013; Slater et al., 2016; Xu et al., 2013); thus, changes in  
 416 temperature,  $T$ , should cause proportional changes in background melting (Jackson et al., 2014). We

417 choose to focus on relative changes in melt rate, rather than absolute changes, because of poor  
418 constraints on important melt rate parameter values (Jackson et al., 2020). We calculate the relative  
419 change in submarine melt rate, *SMR*, following Jackson et al. (2014), as:

$$420 \quad \Delta SMR = \frac{(T_{ib} - T_f) - (T_{nib} - T_f)}{(T_{nib} - T_f)} 100$$

421 where the subscripts *ib* and *nib* indicate simulations with ‘icebergs’ and ‘no icebergs’, respectively, and  
422  $T_f$  is the *in-situ* freezing point, given by:

$$423 \quad T_f = \lambda_1 S + \lambda_2 + \lambda_3 z$$

424 where  $\lambda_{1-3}$  are constants representing the freezing point slope ( $-0.0573 \text{ }^\circ\text{C psu}^{-1}$ ), offset ( $0.0832^\circ\text{C}$ ) and  
425 depth ( $0.000761^\circ\text{C m}^{-1}$ ), respectively (Cowton et al., 2015).  $S$  is the local salinity (horizontally averaged  
426 within 2 km of the terminus) and  $z$  is depth in the water column. It is worth noting that changes in melt  
427 rate calculated using this method assume that all changes in heat supply are accommodated by changes  
428 in submarine melt rates, and so this method provides an indication of the maximum relative changes in  
429 submarine melt rates expected due to changes in ambient ocean temperature.

430 Using this approach, we find that the impact on water properties resulting from iceberg melt  
431 substantially modifies background glacier submarine melt rates. Firstly, in the upper 50 m and using  
432 *BCstandard*, iceberg melt causes a 34.9% reduction in melt rate on average. Even in iceberg scenario  
433 one, iceberg melt causes a 29.5% reduction in melt rate over this depth range. Secondly, between 100  
434 and 200 m depth, iceberg melt causes a 13.5% increase in melt rate on average when using *BCstandard*,  
435 but this increases to 59.2% when using *PWcool* (for which warming of the PW layer due to upwelling  
436 is most pronounced). Changes in iceberg melt rates in the AW layer are minimal, with the most  
437 pronounced effect being a 5.4% increase in the 200-400 m depth range using iceberg scenario five and  
438 *PWwarm*. When averaged through the entire water column, these effects largely compensate for each  
439 other, resulting in a net 3.1% decrease in melt rates with *BCstandard*. Overall therefore, this analysis  
440 suggests that iceberg melt can influence the vertical pattern of glacier terminus background melting by  
441 decreasing melt rates at the surface and increasing them in the PW layer, with minimal changes in the  
442 AW layer.

443 As well as affecting glacier-adjacent water temperatures, iceberg melt likely affects submarine melt  
444 rates in other ways not examined here. For example, the cooling and freshening of the surface and near-  
445 surface layers induced by iceberg melting may prevent or hinder plume surfacing (De Andrés et al.,  
446 2020), and may expedite sea ice formation after the melt season, promoting the development of an ice  
447 mélange. In addition, mechanical iceberg breakup, iceberg calving and iceberg rotation can cause  
448 vigorous mixing of fjord waters which can temporarily increase glacier and iceberg submarine melt  
449 rates (Enderlin et al., 2018), and increases the iceberg-ocean contact area available for melting. Iceberg

450 melt-induced invigoration of fjord circulation can increase oceanic heat flux towards tidewater glaciers  
451 (Davison et al., 2020), likely resulting in faster terminus submarine melting. Icebergs likely also exert  
452 a mechanical influence on the circulation and plume dynamics at the ice-ocean interface (Amundson et  
453 al., 2020), and may prevent plume surfacing (Xie et al., 2019).

454

#### 455 **4.3. Implications for oceanic forcing of ice sheet-scale models**

456 Current state-of-the-art projections of dynamic mass loss from the Greenland Ice Sheet (Goelzer et al.,  
457 2020) are forced by far-field ocean temperature profiles, provided by ocean modelling output that does  
458 not include fjord-scale processes (except for the obstruction of shelf-water intrusion by shallow sills)  
459 (Slater et al., 2019, 2020). The results presented here suggest that such an approach is broadly  
460 appropriate for fjords with maximum iceberg keel depths of less than 200 m and iceberg concentrations  
461 less than ~20% on average, where iceberg modification of glacier-adjacent water properties appears to  
462 be limited other than in the upper several tens of metres (Figs 4 and 6). The majority of Greenland's  
463 fjords likely fall into this category (Mankoff et al., 2019; Sulak et al., 2017). Even in such fjords,  
464 however, this approach would not capture the surface and near-surface cooling caused by iceberg  
465 melting. In order to capture this near surface cooling, one relatively simple modification to such an  
466 approach could be to reduce surface water temperature to close to the *in-situ* melting point during winter  
467 periods, and proportionally to the iceberg surface area at the fjord surface during summer periods.

468 However, in fjords hosting icebergs with keel depth greater than or equal to 200 m and with average  
469 concentrations of more than ~20% (i.e. our iceberg scenario three or higher), iceberg modification of  
470 glacier-adjacent water properties becomes increasingly important. In such fjords that also exhibit  
471 relatively shallow sills, icebergs act to cool glacier-adjacent water throughout the water column, with  
472 the amount of cooling proportional to the draught and concentration of the icebergs, as well as to the  
473 temperature of the ambient water at the fjord mouth (Fig. 4). In such fjords that do not have shallow  
474 sills, the effect is more complicated, with both iceberg melt-induced warming and cooling, depending  
475 on the vertical temperature gradient of the water column and iceberg concentration at depth. Overall,  
476 these changes to the water column temperature can cause non-negligible (up to several tens of percent)  
477 changes in terminus submarine melt rates across the large areas of the calving front that are not directly  
478 affected by plume-inducing subglacial discharge. The vertical pattern of changes to terminus submarine  
479 melt rates (reduced near the surface and increased at intermediate depths) induced by iceberg melting  
480 is expected to exacerbate undercutting of glacier termini, with potentially important impacts on calving  
481 rates (Benn et al., 2017; Ma and Bassis, 2019; O'Leary and Christoffersen, 2013; Todd and  
482 Christoffersen, 2014). Although fjords hosting icebergs this large and numerous are relatively few in  
483 number, it is these fjords (and the glaciers hosted by them) that contribute the most to dynamic mass  
484 loss from the Greenland Ice Sheet (Enderlin et al., 2014; Khan et al., 2020).

485

#### 486 **4.4. Transience vs steady-state**

487 All of the results presented here were extracted from the final ten days of simulations that were run to  
488 a quasi-steady state (i.e. the variable of interest had stabilised). In our domains without sills, steady-  
489 state of temperature and salinity was generally reached after just ten to thirty days. However, our  
490 simulations with sills could take as many as one thousand days to reach such a steady state because  
491 fjord-shelf exchange is reduced. For an equivalent steady-state to be reached in reality, open ocean  
492 conditions, subglacial discharge and iceberg size and distribution would also have to remain quasi-  
493 stable for an equivalent time period. In reality, this is unlikely to occur (particularly in fjords with  
494 shallow sills) because subglacial discharge and coastal and open ocean conditions change on sub-  
495 seasonal to seasonal timescales (Moon et al., 2017; Mortensen et al., 2014; Noël et al., 2016; Sutherland  
496 et al., 2014; Sutherland and Pickart, 2008). In reality therefore, glacier-adjacent water properties in  
497 fjords with shallow sills are likely a complex amalgamation of temporally-evolving source waters,  
498 modified by processes operating within the fjord. In addition, some variations in coastal conditions can  
499 be transmitted towards glaciers very rapidly. During winter, strong wind events on the east coast of  
500 Greenland drive fast shelf-forced flows (or intermediary currents) in glacial fjords, delivering coastal  
501 waters to tidewater glaciers over just a period of a few days, and potentially reducing the magnitude of  
502 iceberg-driven modification (Jackson et al., 2014, 2018). Such currents are strongest in winter, when  
503 hydrographic observations are sparse, so this remains speculative.

504

#### 505 **5. Conclusions**

506 We have used a general circulation model (MITgcm) to quantify the effect of submarine iceberg melting  
507 on glacier-adjacent water properties in an idealised fjord domain. A large range of iceberg  
508 concentrations, keel depths and size-frequency distributions were examined to represent the range of  
509 iceberg conditions found in Greenland's marine terminating glacier fjords. We focused primarily on  
510 iceberg melt-induced changes to glacier-adjacent water temperatures throughout the water column,  
511 because of their principal importance to glacier-submarine melting.

512 Our results suggest that icebergs can substantially modify glacier-adjacent water properties and that the  
513 precise impact depends on iceberg size and on the temperature profile and stratification of water within  
514 and beyond the fjord. In particular, we find that (1) temperature in the upper ~60 m of the water column  
515 is reduced by several degrees Celsius over a wide range of iceberg scenarios; (2) fjords with more and  
516 deeper icebergs are subject to greater iceberg melt-induced modification, which can result in either  
517 cooling or warming at different depths depending on the balance between melt-driven cooling and  
518 upwelling-driven warming, which in turn depends on fjord temperature stratification, and; (3) when  
519 icebergs extend to or below the fjord mouth sill depth, they can cause significant cooling throughout

520 the water column. Particularly with regard to point (2), our results highlight that oceanic forcing of large  
521 fast-flowing glaciers, which contribute the most to ice sheet dynamic mass loss, in existing projections  
522 of tidewater glacier dynamics is strongly affected by ignoring the impact of icebergs on fjord water  
523 properties. The iceberg-induced changes to the vertical temperature profile of glacier-adjacent waters  
524 identified here are likely to reduce submarine melt rates at and near the fjord surface while increasing  
525 them in the PW layer, which may influence the rate and mechanism of calving by exacerbating glacier  
526 terminus undercutting. Our results therefore identify a critical need to develop simple parameterisations  
527 of iceberg-induced modification of fjord waters, and other fjord-scale processes, to better constrain  
528 oceanic forcing of tidewater glaciers.

### 531 **Code availability**

532 MITgcm is freely available at [http://mitgcm.org/public/source\\_code.html](http://mitgcm.org/public/source_code.html). The IcePlume module is  
533 available from Tom Cowton on request. The IceBerg module is available at  
534 <https://zenodo.org/record/3979647#.YWAayNrMKUk> or from Benjamin Davison on request.

535

### 536 **Data availability**

537 Data required to reproduce the analysis and figures in this manuscript will be made available upon  
538 publication.

539

### 540 **Author contributions**

541 BD and TC conceived the study. BD developed the model code with support from TC and AS. BD  
542 designed and conducted the simulations and analysis, and led the manuscript write up. TC, FC, AS and  
543 PN supported the interpretation of the model results and contributed to the preparation of the  
544 manuscript.

545

### 546 **Competing interests**

547 The authors declare that they have no conflict of interest.

548

### 549 **Acknowledgements**

550 BD was funded by a PhD studentship provided by the Scottish Alliance for Geosciences, Environment  
551 and Society (SAGES) and the University of St Andrews, UK. The simulations were conducted on the  
552 Sheffield Advanced Research Computer (ShARC). The authors thank the editor, Nicolas Jourdain, for  
553 considering our manuscript for publication, and Thomas Rackow and one anonymous reviewer for  
554 providing thorough reviews of the manuscript.
