Abstract

In the Karakoram, dozens of glacier surges occurred in the past two decades, making the region one of its global hotspots. Detailed analyses of dense time series from optical and radar satellite images revealed a wide range of surge behaviour in this region: from slow advances longer than a decade at low flow velocities to short, pulse-like advances over one or two years with high velocities. In this study, we present an analysis of three currently surging glaciers in the central Karakoram: North and South Chongtar Glaciers and an unnamed glacier referred to as NN9. All three glaciers flow towards the same [small](#) region but differ strongly in surge behaviour. A full suite of [satellites \(e.g. Landsat, Sentinel-1 and 2, Planet, TerraSAR-X, ICESat-2\)](#) and digital elevation models (DEMs) from different sources ([e.g. SRTM, SPOT, HMA-DEM](#)) are used to (a) obtain comprehensive information about the evolution of the surges from 2000 to 2021 and (b) to compare and evaluate capabilities and limitations of the different satellite sensors for monitoring relatively small glaciers in steep terrain. A strongly contrasting evolution of advance rates and flow velocities is found, though the elevation change pattern is more similar. For example, South Chongtar Glacier had short-lived advance rates above 10 km y⁻¹, velocities up to 30 m d⁻¹ and surface elevations increased by 200 m. In contrast, the neighbouring and three times smaller North Chongtar Glacier had a slow and near linear increase of advance rates (up to 500 m y⁻¹), flow velocities below 1 m d⁻¹ and elevation increases up to 100 m. The even smaller glacier NN9 changed from a slow advance to a full surge within a year, reaching advance rates higher than 1 km y⁻¹. It

40 seems that, despite a similar climatic setting, different surge mechanisms are at play and a transi-
41 tion from one mechanism to another can occur during a single surge. The sensor inter-comparison
42 revealed a high agreement across sensors for deriving flow velocities, but limitations are found on
43 small and narrow glaciers in steep terrain, in particular for Sentinel-1. All investigated DEMs have
44 the required accuracy to clearly show the volume changes during the surges and elevations from
45 ICESat-2 [ATL03](#) data fit neatly [to the other DEMs](#). We conclude that the available satellite data
46 allow for a comprehensive observation of glacier surges from space when combining different sensors
47 to determine the temporal evolution of length, elevation and velocity changes.

50 1. Introduction

51
52 Glacier surges in the Karakoram are widespread (e.g. Sevestre and Benn, 2015) and have been
53 thoroughly documented using historic literature sources and time series of satellite images (Cop-
54 land et al., 2011; Bhambri et al., 2017; Paul, 2020). A large number of publications [provide](#) in-
55 sights into decadal elevation changes (e.g. Bolch et al., 2017; Berthier and Brun, 2019; Brun et al.,
56 2017; Gardelle et al., 2013; Rankl and Braun, 2016; Zhou et al., 2017) and mean annual flow ve-
57 locities (e.g. Dehecq et al., 2015; Rankl et al., 2014) at a regional scale. Using various satellite da-
58 tasetes, several studies have also investigated individual glacier surges at high temporal resolution
59 (e.g. Bhambri et al., 2020; Mayer et al., 2011; Paul et al., 2017; Quincey et al., 2015; Round et al.,
60 2017; Steiner et al., 2018).

FP 25 4 22 9:45 PM

Deleted: provides

61
62 This increasing interest is in part due to the hazard potential of glacier surges, in particular when
63 river damming creates lakes that might catastrophically drain in so-called glacier lake outburst
64 floods (GLOFs) with far reaching impacts (e.g. Bazai et al., 2021; Bhambri et al., 2019 and refer-
65 ences therein; Iturrizaga, 2005), but also due to the increased availability of satellite data for char-
66 acterizing surges in detail (e.g. Dunse et al., 2015; King et al., 2021; Nuth et al., 2019; Rashid
67 et al., 2020; Wang et al., 2021; Willis et al., 2018). The still limited understanding of surges in the
68 Karakoram region (e.g. Farinotti et al., 2020) and the high diversity of observed surge characteris-
69 tics (e.g. Bhambri et al., 2017; Hewitt, 2007; Paul, 2015; Quincey et al., 2015) also contribute to
70 the recent efforts. These studies found that both main types of glacier surges can be found in the
71 Karakoram, sometimes side-by-side: The Alaska type, which might be triggered by a change in the
72 basal hydrologic regime, creates pulse-like surges of a short duration (2-3 years), whereas the
73 thermally-controlled Svalbard type has often active surge durations of many years (e.g. Jiskoot,
74 2011; Murray et al., 2002; Raymond, 1987; Sharp, 1988). Although the physical reasons for the
75 differences and variability of surges in the Karakoram are yet unknown (e.g. glacier properties,
76 thermal regime, mass balance history), many glaciers in the Karakoram have surged repeatedly,
77 sometimes at surprisingly constant intervals and over centuries (e.g. Bhambri et al., 2017; Paul,

80 2020). On average, surges in the central Karakoram repeat after 40 to 60 years, but intervals can
81 range from less than 20 to more than 80 years.

82
83 In the thermally controlled case, it is sometimes difficult to distinguish a regular advance from a
84 surge, as the transition can be gradual (Lv et al., 2020). Whether an advance (stimulated by a posi-
85 tive mass budget) is indeed a surge might be determined by comparison with the behaviour of
86 neighbouring glaciers. As thresholds on advance rates or ice flow speedup might not be efficient to
87 distinguish (slow) surges from advances in the Karakoram, the typical mass redistribution pattern
88 of a surge (from an upper reservoir to a lower receiving zone) as obtained from differencing digital
89 elevation models (DEMs) acquired a few years apart (e.g. Gardelle et al., 2013) is a more reliable
90 identifier (Lv et al., 2019; Goerlich et al., 2020). Usually, the surface in the upper regions of a
91 glacier does not lower significantly during a regular advance (Lv et al., 2020). A further method to
92 discriminate surges from a usual advance is related to a strong increase in crevassing and devel-
93 opment of shear margins. However, these are only visible in very high-resolution satellite images
94 or time-series of SAR data (Leclercq et al., 2021).

95
96 In this study, we present (a) a comparative analysis of the on-going surges of three glaciers in the
97 central Karakoram: North and South Chongtar Glacier and a small, unnamed glacier referred to
98 here as NN9. We present a comparative analysis of their changes in length, advance rates, flow
99 velocities and surface elevations to elucidate the respective similarities and differences in surge
100 behaviour. As a second aim of this study, we (b) investigate the feasibility of various satellite sen-
101 sors and DEMs to follow the temporal evolution of the surges comprehensively. Included are opti-
102 cal (Sentinel-2, Landsat, Planet cubesats) and synthetic aperture radar (SAR) imaging sensors
103 (Sentinel-1, TerraSAR-X), altimeter data from ICESat-2 and DEMs from the Shuttle Radar To-
104 pography Mission (SRTM), the Satellite Pour l'Observation de la Terre (SPOT), the High Moun-
105 tain Asia DEM (HMA-DEM) and the Advanced Spaceborne Thermal Emission and reflectance
106 Radiometer (ASTER). [The latter is an external dataset provided](#) by Hugonnet et al. (2021).

107
108

109 2. Study region

110

111 The study region is located in the central Karakoram, north of the Baltoro Glacier, at about [35.94°](#)
112 N and 76.33° E (Fig. 1). East of the study region stands the second highest mountain in the world,
113 the 8611 m high K2. Slopes of the surrounding terrain are very steep and snow avalanches from
114 the surrounding rock walls are a major source of glacier nourishment. Mass changes over the past
115 20 years derived from satellite data using the geodetic method show more or less constant near-
116 zero mass budgets in the study region (Hugonnet et al., 2021), confirming the continuation of the
117 'Karakoram Anomaly' (i.e. the balanced mass budgets) in this region (Farinotti et al., 2020).

120

121

Fig. 1: Overview study region

122

123 Most precipitation in the study region is brought by westerly air flow during winter, but the mon-
124 soon brings moist air from the southeast also during summer (Maussion et al., 2014), falling as
125 snow at the high elevations of the rock walls surrounding most glaciers. However, due to the good
126 protection from nearly all directions, the amount of snowfall in the study region is limited and a
127 dry-continental climate can be expected (e.g. Sakai et al., 2015). As surge-type glaciers are abun-
128 dant (Copland et al., 2011; Bhambri et al., 2017) and repeat intervals are comparably short (Paul,
129 2020), several glaciers in the Karakoram are typically actively surging at any given time.

130

131 The three glaciers investigated here (North/South Chongtar, NN9) have mean elevations around
132 5500 m and are surrounded by mountain ridges with elevations between 6000 and 7500 m above
133 sea level. South Chongtar Glacier (shortened to South Chongtar in the following) is the largest
134 with an area of ~ 31 km² and a length of more than 14 km at minimum extent, but it has a narrow
135 tongue with a near-constant width of about 800 m. The glacier is mainly east-west oriented in its
136 upper part, bending towards south-north near the terminus. North Chongtar lies north of South
137 Chongtar and is connected to it in its accumulation area. It flows from southeast to northwest, co-
138 vers an area of ~ 10 km², has a length of 4.5 km at minimum extent and is about 400 m wide. The
139 unnamed glacier NN9 is located on the opposite side of the main valley and flows roughly from
140 west to east. The glacier is about 3.5 km long at minimum extent with an area of 4 km² and a ~ 300
141 m wide tongue. Table 1 summarises further characteristics and topographic properties.

142

Table 1: Basic properties of the three investigated glaciers

144

145 At their [historically recorded](#) maximum extent the three glaciers reach Sarpo Laggo Glacier, a
146 compound-basin valley glacier with a size of 122.3 km². This glacier experienced a massive surge
147 shortly before 1960 (Paul, 2020) and a smaller, more internal one (i.e. not reaching the terminus),
148 between 1993 and 1995 (e.g. Paul, 2015; [Bhambri et al., 2017](#)). According to Paul (2020), South
149 Chongtar had a rapid advance during a surge that started in 1966 with a short active phase of about
150 two years followed by a quiescent phase with continuous down-wasting and retreat. During this
151 surge it partly compressed the ice from Sarpo Laggo and deformed a moraine from [the](#) Moni Glac-
152 [ier tributary](#) (see Fig. 1), leaving an impressive surge mark. In contrast, North Chongtar started
153 advancing about 55 years ago but has not yet reached Sarpo Laggo. The Shipton map from 1937
154 (Shipton, 1938) shows North Chongtar in contact with it, indicating that the terminus might reach
155 it again. The glacier NN9 had its last surge from about 1961 to 1971 (leaving a small surge mark
156 on Sarpo Laggo) and retreated in its quiescent phase until 2000, when it started to advance slowly.
157 The two glaciers to the south of NN9 (NN7 and NN8 in Paul, 2020) both surged around 1955, and

158 again in 1998 and 1980, respectively. NN8 also surged after 2002, indicating a surge cycle of only
159 20-25 years. The next surge of NN8 can thus be expected [in a few years](#), at least if environmental
160 conditions prevail.

162

163 3. Datasets

164

165 In this section, we describe the satellite and auxiliary datasets used to derive time series of glacier
166 outlines, surface flow velocities and elevation changes in the study region. Figure 2 shows the
167 temporal coverage of each dataset, and the periods selected for the analysis. Changes in glacier
168 extent have been mapped for the active (advance) phases of the three glaciers, starting with Land-
169 sat Multispectral Scanner (MSS) images from 1973 for North Chongtar Glacier. The earliest da-
170 taset used to derive flow velocities and elevation changes were acquired in 2000, [based on the](#)
171 [Landsat 7 Enhanced Thematic Mapper plus \(ETM+\) panchromatic band and the SRTM DEM, re-](#)
172 [spectively.](#)

173

174 *Fig. 2: Timeline of datasets used*

175

176 3.1 Glacier extent and centrelines

177 We used glacier outlines from the updated Glacier Area Mapping for Discharge from the Asian
178 Mountains (GAMDAM2) inventory by Sakai (2019) as a starting point for all glacier extents. This
179 dataset was locally improved (removing rock outcrops and seasonal snow) using a Landsat 8 im-
180 age acquired on 21 October 2020 (Fig. 1). Given the unknown final length of the glaciers, we dig-
181 itized [likely](#) maximum extents for the three glaciers, avoiding overlapping polygons in their termi-
182 nus regions. The virtual extents were guided by maximum extents of previous surges described by
183 Paul (2020).

184

185 Changes in extent were derived from time series of spatially consistent Landsat data (MSS, TM,
186 ETM+ and Operational Land Imager (OLI)) from path-row 148-35. [The slightly shifted](#) Sentinel-2
187 [scenes \(sensor Multi Spectral Imager, MSI\) from tile 43SFV, were used to bridge a gap in availa-](#)
188 [bility of](#) cloud-free Landsat scenes after February 2021. [The shift of about 50 m was manually sub-](#)
189 [tracted to obtain a correct time series of length changes. The spatial resolution of the optical sen-](#)
190 [sors used for this purpose is 60 m \(MSS\), 30 m \(TM\), 15 m \(ETM+, OLI\) and 10 m \(MSI\).](#) The
191 list of satellite scenes used for determination of geometric changes (outlines, length changes) is
192 given in Table S1 of the Supplemental Material.

193

194 The centrelines for NN9, South and North Chongtar were manually digitized starting from the
195 highest points of each glacier down to the virtual maximum extent. The centrelines were divided

201 into equidistant points of 100 m at which values for velocity and elevation were extracted.

202

203 3.2. Flow velocity

204 Time series of optical and SAR data were used to derive glacier flow fields (see Table S2). Land-
205 sat 7 and 8 scenes, Sentinel-2 and TerraSAR-X (TSX) were used (Fig. 2) to determine pre-surge
206 flow velocities of South Chongtar and advance/surge phase velocities for all glaciers. Images from
207 Planet cubesats were used for a comparison of results with Sentinel-2 and some gap filling in the
208 time series rather than for a full documentation of the active surge of South Chongtar. [The related
209 optical images were acquired in summer or autumn for the pre-surge phase of South Chongtar and
210 all year during its surge \(Table S2\).](#)

211

212 From TSX co-registered single-look slant range complex (SSC) images acquired in StripMap
213 mode, with across- and along-track resolution of up to 3 m are used. The selected image pairs are
214 from two different tracks, cover the study region in the descending direction and were acquired in
215 [winter 2011, autumn 2012 and spring 2014](#) (Table S2). [The three SAR image pairs from TSX were
216 acquired in winter, autumn and spring.](#) Time series of Sentinel-1 single-look complex (SLC) data
217 acquired in interferometric wide (IW) swath mode were used to test its feasibility to derive flow
218 velocities and to create an animation of the surge that is unobstructed by clouds. The Sentinel-1
219 IW SLC data have a nominal ground resolution of 5 m x 20 m.

220

221 3.3 Elevation information

222 To follow elevation changes of the glaciers before and during the surge, we analysed several
223 DEMs from both optical and SAR sensors (Table 2). We used the following DEMs with known
224 acquisition dates: The SRTM1 DEM at 1 arcsec (~30 m) resolution from February 2000 (USGS,
225 2017), a SPOT5-HRS DEM from [October 2010](#) (Gardelle et al., 2013; we used their version v2 for
226 rugged areas), a SPOT6 DEM from October 2015 (Berthier and Brun, 2019), and a SPOT7-
227 derived DEM from October 2020 that was generated for this study. In addition, we used the HMA-
228 DEM mosaic (Shean, 2017) as a reference for DEM co-registration analysis due to its superior
229 spatial resolution and accuracy over stable terrain (off-glacier) compared to the other DEMs (Fig.
230 S1). The HMA-DEM is composed of various DEM datasets mostly acquired during 2015 (Feb.,
231 April, July, and Aug.) in this region. Elevation values along the centrelines are extracted from these
232 DEMs and DEM differences are calculated for the periods 2000-2010, 2010-2015 and 2015-
233 2020. For comparison, we also analysed elevation changes derived from ASTER time series by
234 Hugonnet et al. (2021). These provide additional information about the [periods 2000-2004](#) and
235 [2005-2009 \(full calendar years\)](#) as well as from 2000 to 2019, before the surge of South Chongtar.

247 We also analysed whether altimetry data from ICESat-2 could be used to reveal elevation changes
248 at a higher temporal resolution. The Advanced Topographic Laser Altimeter System (ATLAS)
249 instrument on-board ICESat-2 acquires elevation profiles at a 91-day temporal resolution since
250 October 2018. Each satellite overpass results in three beam pairs that are separated by 3.3 km and
251 90 m between/within pairs, respectively (Markus et al., 2017). The ICESat-2 ATL06 dataset pro-
252 vides geolocated land ice surface heights with 40 m spatial resolution in profile direction. Figure
253 S2 shows the ATL06 dates and elevations of data points crossing North and South Chongtar, and
254 the two closest repeating pairs of tracks on South Chongtar. Due to the systematic off-pointing at
255 mid-latitudes, ICESat-2 tracks are not repeated exactly in our study area and the ATL06 data alone
256 proved too sparse, both geographically and temporally, for further analysis of the surges.

257
258 The ICESat-2 ATL03 Global Geolocated Photon Data (Neumann et al., 2021), from which the
259 ATL06 dataset is a higher-level derivative, provides surface elevation measurements from individ-
260 ual photons every 0.7 m along the elevation profiles, revealing details of the surface topography of
261 the glaciers. The ICESat-2 surface elevations fall into the time gap of the DEMs between 2015 and
262 2020, thus providing additional temporal information on the surge development. In total, we found
263 42 intersections with the centrelines of the three investigated glaciers: 23 on South Chongtar (from
264 seven dates), 13 on North Chongtar (from six dates), and 6 on NN9 (from three dates).

267 4. Methods

268 4.1 Glacier extent

269 The timing of the selected images used to digitize glacier extents varies strongly depending on the
270 advance rates. To have at least a two-pixel change in frontal position, [\(which is sufficient for sound](#)
271 [change detection\)](#), it varies from several years for the slow advance of North Chongtar to about 16
272 days for the surge phase of South Chongtar. [For North Chongtar also the spatial resolution of the](#)
273 [sensor matters to some extent, as two pixels translate to a required advance of 120 and 60 m for](#)
274 [MSS and TM, respectively.](#) Due to frequent cloud cover, different scenes had to be used for the
275 individual glaciers (Table S1). For the digitization, the polygon referring to the virtual maximum
276 extent of each glacier was split into a multi-polygon by digitizing the smaller extents visible on the
277 respective satellite images.

278
279 Length changes between two terminus positions from t_1 and t_2 were derived manually using the
280 distance tool in ArcGIS. Several values were obtained for each change and a suitable average as-
281 signed (values usually varied by about ± 10 m). We only used the Landsat 7 and 8 time series for
282 this as the Landsat Collection 1 data had a spatial shift compared to Sentinel-2 (e.g. Paul et al.,
283 2016). The length change values from t_1 to t_2 were divided by the temporal difference ($t_2 - t_1$), con-
284 verted to mean annual advance rates and assigned to the date that is halfway between t_1 and t_2 .

FP 25 4 22 9:45 PM

Deleted: ,

286 Cumulative changes were obtained by summing up the individual length changes.

287

288 4.2 Velocities

289 Flow velocities typically span two to three orders of magnitude, e.g. from $<0.1 \text{ m d}^{-1}$ for near stag-
290 nant glaciers to $>10 \text{ m d}^{-1}$ during a surge. When using offset-tracking (e.g. [Strozzi et al., 2002](#))
291 [When using offset-tracking \(e.g. Strozzi et al., 2002\) for both Sentinel-1 and TSX or image corre-](#)
292 [lation for optical data \(Debella-Gilo and Käab, 2012\)](#), this range can to some extent be accounted
293 for by varying the search window size or the time between the acquisition dates of the image pair.
294 If glaciers with very different flow velocities are in the study region, it might be required to use
295 images from different dates for the analysis or an adaptive search window (Debella-Gilo and Käab,
296 2012). In the following, we describe some basics of the processing lines applied for optical and
297 SAR sensors.

298

299 The normalized cross-correlation algorithm implemented in the correlation image analysis soft-
300 ware (CIAS, Käab and Vollmer, 2000) is used to calculate the glacier surface displacement be-
301 tween optical satellite image pairs (Fig. S3 is illustrating the workflow). The satellite images were
302 not co-registered as we assume that they are corrected for topographic distortion, and therefore the
303 displacement calculated between two images is the actual horizontal displacement without any
304 influence of topography. To check co-registration, abundant stable terrain was included in the cor-
305 relation. The displacements are estimated at a spatial resolution of 100 m while the size of the
306 search area is set in relation to the maximum displacement estimated between two satellite scenes.
307 Dividing the displacement by the temporal difference between the image pairs (Table S2) gives
308 velocity in m d^{-1} .

309

310 With optical data, clouds, cast shadows and changes in snow cover lead to false detections or bi-
311 ased measurements of the calculated displacement fields. These mismatches are removed in post-
312 processing by setting a threshold of the maximum correlation coefficient (<0.5) and velocity. For
313 Sentinel-2 data, elevated objects such as clouds are detected by applying CIAS between band 4
314 and band 8 of the same Sentinel-2 scene. The calculated perspective displacements (both bands are
315 recorded at slightly different positions of the sensor) are then used to mask the clouds. For all sat-
316 ellite data, spatial filtering based on a moving median window as well as temporal filtering are ap-
317 plied to remove additional outliers and noise (Fig. S3).

318

319 Surface flow velocities for TSX data were derived by an iterative offset-tracking technique devel-
320 oped for SAR data (Wuite et al., 2015). This method does not require coherence and is thus also
321 capable of acquiring flow velocity data over longer time spans and in regions with fast flow. The
322 method is based on cross-correlation of templates in SAR amplitude images and provides both the
323 along-track and line-of-sight velocity components from a single image pair. We used a template

FP 25 4 22 9:45 PM

325 size of 96x96 pixels for generating velocity maps with 50 m grid spacing and applied a 9x9 in-
326 verse-distance median filter in the post-processing step to remove outliers and fill in small gaps.
327 For Sentinel-1, the same method was applied but tests with various image template sizes were per-
328 formed with an image pair acquired on 4. and [16. November](#) 2020 during the peak of the surge
329 (Fig. S4).

331 4.3 Elevation data

332 We used the MicMac software to generate the SPOT 2020 DEM from the raw imagery (Rupnik et
333 al., 2017). The pre-processing of all DEMs follows the standard processing steps for DEM differ-
334 encing. All DEMs were projected to UTM 43N (EPSG 32643), elevations were vertically trans-
335 formed to the WGS 84 ellipsoid and DEMs were co-registered to the HMA DEM using OPALS
336 (Pfeifer et al., 2014). Specifically, we applied least squares matching to estimate the full 3D affine
337 transformation parameters that minimize the errors with respect to the reference DEM over com-
338 mon stable areas. These were manually digitized off-glacier excluding slope values larger than 40
339 degrees (Fig. S5). [Because of data voids, we also had to exclude](#) large parts of the accumulation
340 areas of some glaciers in the case of the SPOT 2010 and 2015 DEMs.

FP 25 4 22 9:45 PM
Deleted: .

342 All DEMs were resampled, clipped and aligned to the same 30 m grid and a high-resolution 5 m
343 grid for the HMA DEM and SPOT 2020. We did not correct the SRTM DEM for microwave pen-
344 etration into ice and snow (Gardelle et al., 2012), as the effect is small compared to the elevation
345 differences caused by the surges [and uncertain, i.e. it is not systematic and any for example eleva-
346 tion dependent correction can not be justified either](#). Elevation values were extracted along the
347 centrelines and subtracted from SRTM.

349 To estimate volume changes resulting from the surges, volume gain and loss (i.e., summing up all
350 positive and negative values within the tongues) were calculated for each glacier tongue with ad-
351 justed extents and glacier-specific epochs (Fig. S5). For comparison, we included the glaciers NN7
352 and NN8 (see Fig. 1) in the analysis as they also surged during the study period.

354 As the ICESat-2 ATL06 datasets did not provide useful results, only the ATL03 dataset was fur-
355 ther processed using python libraries geopandas (Jordahl et al., 2021), rasterio (Gillies et al., 2021)
356 and shapely (Gillies et al., 2021a). The photon elevations were filtered to only retain elevation
357 samples classified as likely land or ice surfaces (parameters `signal_conf_ph` / `sig-
358 nal_conf_ph_landice >1`) and classified into glacier and off-glacier samples using maximum glaci-
359 er outlines. On the bright glacier surface, both the weak and strong laser beams yield sufficient
360 photon returns for complete elevation profiles. This is less true for moraines / rocky areas (profile
361 3 in Fig. S6), where the weak beam yields considerably fewer surface returns.

FP 25 4 22 9:45 PM
Deleted: /

372 Elevation values were sampled for all elevation points (containing a DEM cell) and the AMES
373 stereo pipeline (version 2.7.0, Shean et al., 2016) was used to co-register the elevation profiles (on-
374 ly off-glacier samples) with the already co-registered DEMs used in this study (no co-registration
375 offset was found). The profiles were intersected with the glacier centrelines to compare the ATL03
376 elevation samples with the DEMs. The median of all elevation samples on each profile within a 10
377 m buffer from the centreline are used as surface elevations at the intersection points.

378

379 **4.4 Uncertainties**

380 The uncertainty of the length change data has been determined by measuring for each glacier and
381 each time step different points at the terminus. From the range of values, a reasonable mean value
382 was determined manually. Glacier terminus positions were digitized only once and used only for a
383 qualitative illustration (outline overlay) of the changes, i.e. we have not explicitly calculated un-
384 certainties of glacier extents. As a range of sensors with different spatial resolutions is used for the
385 digitizing (e.g. Landsat MSS, ETM+, OLI and Sentinel-2), the uncertainty varies with the sensor.

386

387 Based on the assumption that measurement errors over glaciers and other terrain are common
388 (Paul et al., 2017), we assessed the uncertainties of glacier flow velocities from stable terrain ve-
389 locity observations, where flow velocities are supposed to be zero, using the same stable areas as
390 used for DEM co-registration (Fig. S5). Uncertainties are derived as measures of median and a
391 robust standard deviation based on the median absolute deviation (MAD), which is a bit less sensi-
392 tive to outliers (e.g. Dehecq et al., 2015). Co-registration accuracy of the DEMs was computed
393 from elevation differences calculated over stable terrain (off glacier) with slopes smaller than 40°
394 (Fig. S5).

395

396

397 **5. Results**

398

399 **5.1 Changes in glacier extent and morphology**

400 In Fig. 3 the temporal evolution of terminus positions is depicted as an overlay of extents showing
401 slow advances of NN9 (starting in 2000) and North Chongtar (since 1973) along with a rapid ad-
402 vance of South Chongtar (starting mid-2020). For better visibility, the retreat phase of South
403 Chongtar from 2000 to mid-2020 is not shown. Snapshots of the geometric evolution can be found
404 in Fig. S7 for the time period before the surge of South Chongtar (1993-2019) and in Fig. S8 for
405 the time during its surge (2020-2021). The related cumulative length changes for all three glaciers
406 are shown in Fig. 4a for their advance phases, whereas Fig. 4b only shows advance rates for the
407 glaciers NN9 and North Chongtar (they were out of scale for South Chongtar).

408

409

Fig. 3: Multi-temporal outline overlay advance phase

410

411 **South Chongtar** entered its quiescent phase after its 1966/67 surge and exhibited constant thin-
412 ning with limited frontal retreat over several decades. After 30 years (in 2000) the former surge
413 lobe was still largely ice filled, though increasingly debris covered. Driven by further thinning, a
414 clear retreat of the terminus (remaining clean ice) became visible after 2000, reaching about -800
415 m by 2009 and -2300 m by mid-2020. During this retreat phase, its middle part always showed
416 some residual flow, i.e. it was not completely stagnant. In 1993 a deformation of the medial mo-
417 raine started moving forward, about 300 m by 2009 and 500 m by 2019.

418

419 In 2017, a new surge developed with the typical funnel-shaped appearance of the front. While the
420 lowest part of the glacier was still thinning and retreating in 2019, the surge front reached the ter-
421 minus in July 2020 and the front started advancing by about 3 km in 10 months (Fig. 4a) with ad-
422 vance rates of up to 12.6 km yr^{-1} (35 m d^{-1}) in early Nov. 2020. During this time the lower part
423 widened massively and the entire surface became heavily crevassed. The front advanced into its
424 former surge mark on Sarpo Laggo Glacier and pushed the ice surrounding it towards the opposite
425 side of the valley. By June 2021 advance rates decreased considerably, but the terminus was still
426 advancing.

427

428 *Fig. 4: Cumulative length changes and advance rates*

429

430 **North Chongtar** on the other hand, advanced at a more or less constant rate of 30 m yr^{-1} until 2004
431 when it passed a total of 800 m since 1973 (earliest MSS image, see Table S1). A very high-
432 resolution satellite image from 2001 is available in Google Earth and shows some crevassing near
433 the terminus but not a surging glacier. There is no indication of a melt water stream leaving the
434 glacier snout. After 2005, advance rates increased linearly and we assign this as the onset of the
435 surge phase. This increase resulted in a nearly completely crevassed surface and widespread shear
436 margins. Both are also visible in the 15 m resolution Landsat panchromatic bands, and, even bet-
437 ter, in very high-resolution images from 2011 and 2016 available in Google Earth. In 2013 the
438 terminus reached a step in the valley slope, creating a deep transverse crevasse that seemed to sep-
439 arate the lowest part of the tongue but actually didn't. By 2021 nearly the entire surface was still
440 crevassed and the glacier had advanced by a further 1600 m since 2004, i.e. 2.4 km in total.

441

442 The small valley **glacier NN9** slowly retreated until 1998 and started advancing a year later at
443 about a constant rate of 40 m yr^{-1} until 2016 (Fig. 4). Up to this year, its lowest parts had some cre-
444 vasses but looked otherwise like a usual advancing glacier. This changed a year later when the
445 glacier thickened considerably, developed shear margins and started advancing at a much higher
446 rate of up to 1000 m yr^{-1} in 2021, indicating the start of the surge phase. The increasingly crevassed
447 surface also became visible in Sentinel-2 images and with the 15 m Landsat 8 band. The total ad-

448 vance from 1999 to 2018 was 800 m followed by a further 500 m until June 2021. In July the
449 frontal advance accelerated further reaching nearly 3 km y^{-1} in August 2021, whereby the lower
450 part of the tongue separated from the main glacier and slid down the remaining kilometre in about
451 a month. More ice is following from higher elevations, possibly leading to some interaction with
452 the still advancing terminus of South Chongtar.

453

454 5.2 Flow velocities

455 5.2.1 NN9 and North Chongtar

456 Selected flow velocity maps for the two glaciers are shown in Fig. 5 and related velocity profiles
457 along the centreline of the main trunk can be seen in Figs. 6a and b for NN9 and North Chongtar,
458 respectively. The c. 300-400 m wide tongue of NN9 is at the edge of the possibilities for deriving
459 flow velocities with offset-tracking (and a 100 m grid) from the optical sensors, but the high reso-
460 lution of TSX StripMap acquisitions provides near-complete spatial coverage (Fig. 5b). Due to
461 local cloud cover several of the optical image pairs selected for South Chongtar could not be used
462 for NN9 and North Chongtar.

463

464 Though scattered, the values derived from Landsat 7 (Fig. 5a), Sentinel-2 (Fig. 5c) and Landsat 8
465 (Fig. 5d) look reasonable. Pre-surge values are around 0.1 m d^{-1} with Landsat 7 (2000-2002) and
466 TSX (2011 and 2012) and a bit higher (up to 0.2 m d^{-1}) with Sentinel-2 in 2017 (Fig. 6a). After-
467 wards values in the lower part of NN9 (between 2.5 and 4 km) start increasing to 0.4 m d^{-1} , reach-
468 ing 0.8 m d^{-1} between August and October 2020. The upper glacier started accelerating in autumn
469 2020 with a near-linear increase up to the terminus (Fig. 6a), indicating surge activation in the
470 lower part of the glacier. The increased crevassing of NN9 is also visible in the higher intensity
471 values of the Sentinel-1 animation towards the latest images (see Supplemental Material).

472

473 *Fig. 5: 2D flow velocity maps 2000-2019 for all glaciers*

474

475 For the larger North Chongtar, a slightly better coverage can be obtained from the optical sensors
476 than for NN9. The most homogenous flow fields are derived by TSX (Fig. 5b) indicating higher
477 flow velocities of up to 0.4 m d^{-1} in its lower two thirds up to the terminus in 2012. The profiles in
478 Fig. 6b from Landsat 7 show similar values. Velocities derived from Sentinel-2 between 2016 and
479 2019 are lower in the region from 3 to 5.5 km. There is a zone with very low velocities between
480 4.5 and 5 km and acceleration [further down](#). From August 2019 to October 2020 flow velocities
481 are between 0.8 and 1 m d^{-1} near the terminus, indicating that this region is fast flowing and ad-
482 vancing, whereas the upper regions are still moving with 0.2 to 0.4 m d^{-1} .

488 5.2.2 South Chongtar

489 The much larger South Chongtar glacier was adequately captured by the optical sensors so that a
490 more continuous flow field could be derived (Fig. 5) and pre-surge flow evolution could be fol-
491 lowed in detail (Fig. 7a). Comparing the maps in Fig. 5, a slow but steady increase of flow veloci-
492 ties from 2000 to mid-2019 over large parts of the glacier can be seen, starting at about 0.15 m d^{-1}
493 and ending at 0.4 m d^{-1} . These values are similar to the other two glaciers, but affect a larger re-
494 gion. The temporal evolution shown in Fig. 7a confirm this observation; pre-surge flow velocities
495 are highest (up to 0.4 m d^{-1}) near the middle of the glacier (around 8 to 10 km) and decrease gradu-
496 ally to 0 m d^{-1} at its highest and lowest points. In the region between 11 and 14 km the gradual in-
497 crease of flow velocities can be followed from 2000/02 (with Landsat 7) to 2014 (with TSX).
498 Mean annual values with Landsat 8 from 2013 to 2014 match perfectly with mean monthly TSX
499 values from April to May 2014. Landsat 8 velocities from 2013 to 2016 and Sentinel-2 from 2016
500 to 2019 show the continuation of the slow velocity increase over the entire glacier length, reaching
501 0.4 m d^{-1} in 2018/19. A direct comparison with Landsat 8 over nearly the same period (grey dots in
502 Fig. 7a) is shown on top of the curve from Sentinel-2, indicating again a near-perfect match. In
503 August 2019 the gradual increase changed at first rapidly to 0.8 m d^{-1} and then more slowly to 1.1
504 m d^{-1} between September 2019 and June 2020. With the stagnant terminus still at 13.5 km, the
505 strong velocity increase behind the front marks the onset of the surge around August 2019.

506
507 *Fig. 7: Velocities South Chongtar*

508
509 The last curve from Fig. 7a is repeated in Fig. 7b (dark blue at the bottom), as we had to switch the
510 scale for better visibility of velocities during the surge phase. Flow velocities increased to about 4
511 m d^{-1} by July 2020. In August 2020 we could derive detailed flow fields from Sentinel-2 images
512 acquired only 5 days apart. A sharp surge front with maximum velocities formed, reaching values
513 of more than 25 m d^{-1} in August/September 2020. With peak velocities near 30 m d^{-1} as derived
514 locally from Planet imagery (Fig. S10), South Chongtar Glacier had likely one of the highest flow
515 velocities ever measured in the Karakoram region. Behind this maximum, flow velocities de-
516 creased about linearly back to $\text{km } 3$ along the centre line. When the surge front reached the termi-
517 nus in July 2020, a rapid advance started (see 5.1). Velocities dropped to 15 m d^{-1} by November
518 2020 and below 10 m d^{-1} by January 2021. Afterwards, maximum velocities are found near km 15
519 and decreased only slowly at this location and over large parts of the glacier length (back to km 6)
520 at about the same rate, indicating that the active surge was on-going. Around km 10, along the cen-
521 tre line, velocity is still around 5 m d^{-1} in early May 2021 or 40 times higher than during the quies-
522 cent phase (Fig. 7b). The related Hovmöller diagram for the surge phase in Fig. 7c confirms the
523 strong pulse-like acceleration in August 2020 with a rapid decline afterwards. The corresponding
524 2D plots of flow velocities during the surge phase of South Chongtar (Fig. 8) also reveal the rapid
525 velocity increase by September 2020 and the decrease afterwards.

Fig. 8: 2D maps of surface velocities South Chongtar

The spatial distribution of highest flow velocities of Figs. 8b and c are not symmetric to the centre line, indicating that the deformation-related maximum flow velocity in the centre of a glacier has reduced relevance here. This somehow counterintuitive behaviour indicates that during a surge basal sliding is the process dominating over deformation. Other possibilities are a decreased resistance of the valley floor or because of the topography redirecting the mass flow from northwest to north. The cross-profile flow velocities (Fig. 9) reveal that this pattern persists throughout the entire surge.

Fig. 9: 1D cross-profile velocities South Chongtar (surge phase)

5.3 Elevation changes

In the three panels of Fig. 10 we show differences in elevation between the SRTM DEM and the other four DEMs along the centrelines of the three glaciers. Additionally, differences from selected ICESat-2 ATL03 points are plotted. Figure 11 shows related elevation change maps for 2000 – 2010, 2010 – 2015, 2015 – 2020 and 2000 – 2020. DEM differences obtained from ASTER in an independent study (Hugonnet et al., 2021) have been used for comparison.

The elevation data for **NN9** (Fig. 10a) show virtually no change in its upper part down to 3.5 km where the terminus was located in 2000. The ICESat-2 data adds no further information here, as all available data points are located in the upper part. Below this region, the ‘elevation gain’ due to the advancing snout can be followed down to km 4.5 in 2020. The small region of elevation gain by the advancing tongue is also visible in each of the maps in Fig. 11. The elevation differences between the two high-resolution DEMs from 2015 and 2020 in Fig. 11c reveal some surface lowering in the upper part (about 10-15 m), but over the longer period 2000 to 2020 (Fig. 11d) this lowering nearly disappears (i.e. is smaller than the SRTM uncertainty). So for NN9 the typical mass transfer of a surge could not be observed until October 2020 and elevation changes look like expected for a usual advance rather than a surge.

For **North Chongtar** (Fig. 10b) the situation is similar, but a surface lowering of about 40 m can be observed at higher elevation. The SPOT data from October 2015 and ICESat-2 data points from December 2018 at 4.2 km indicate that the largest changes happened between 2015 and 2018. Accordingly, this change is well visible in the high-resolution 2015-2020 DEM difference (Fig. 11c) and the differences over the full 2000-2020 period (Fig. 11d). However, also here the elevation gain in the lower glacier part is comparably localized and largely due to the advance of the terminus.

FP 25 4 22 9:45 PM
Deleted: ,

572

573

Fig. 10: 1D profile elevation changes compared to SRTM

574

575 **South Chongtar** shows profiles (Fig. 10c) and surface change patterns (Fig. 11) that are in line
576 with a typical surge, maybe apart from the fact that the thickening of the upper glacier regions is
577 limited. The 2000 to 2010 change map (Fig. 11a) shows a slightly bluish upper part and some arte-
578 facts. Over the longer 2000 to 2015 period the elevation gain from 4 to 12 km is about 20-30 m
579 (Fig. 10c), but further down a significant surface lowering (>50 m) can be observed between 13
580 and 18 km. This lowering is also visible in the 2D map of Fig. 11a, marking at its upper point the
581 position where the active ice starts, i.e. where the surface lowering is compensated by the mass
582 flux. The 2020 surge moved ice between 3 and 8 km towards its lower part between 10 and 16 km,
583 causing a surface elevation decrease of 20-40 m in the reservoir zone and an increase of up to 130
584 m at km 14.

585

586 The ICESat-2 data points constrain the surface elevation evolution in time (Fig. 10c): The tongue
587 was still only slightly thicker at 12 km in March 2019, as surface lowering of the upper part (at 5.7
588 km) had not started in February 2020 and the terminus had not advanced by March 2020. Between
589 6 and 14 km we find a smooth linear increase of the elevation differences (Fig. 10c) - but the ICE-
590 Sat-2 data points at 9.5 km show a slight surface lowering between December 2019 and August
591 2020, indicating that the surge front passed this part of the glacier already before the end of August
592 2000. The 2015 to 2020 elevation change map (Fig. 11c) reveals that elevation changes mostly
593 occurred over this time period. Due to the opposite elevation change pattern before 2015, elevation
594 changes over the full period 2000-2020 are less pronounced. The constantly down-wasting Sarpo
595 Lago Glacier in the valley floor shows an elevation loss of up to 100 m over this period.

596

597

Fig. 11: 2D elevation change maps

598

599 **5.4 Volume changes**

600 In Table 3 the results of the calculated volume changes are listed, differentiated for the gain and
601 loss part. They add some quantitative information over a larger part of the glacier surface (see Fig.
602 S5). With the timing of the DEMs not always synchronous with the start/end of a surge, the calcu-
603 lated values can be underestimated due to the overlap of surge phases. For example, the volume
604 gain in the lower part of South Chongtar from 2000 to 2020 includes the volume loss between
605 2000 and 2019. For this reason we only analyse the 2015 to 2020 changes for South Chongtar

606

607 For NN9 no mass transfer from an upper region is found. We have a near zero mass loss compared
608 to a clear volume gain of 0.03 km³. For the continuous advance/surge of North Chongtar the vol-
609 ume gain is a bit higher than the loss resulting in a small overall volume gain over the full 20-year

610 | period (Fig. 11d). However, Fig. 11c reveals that compensation effects are included. Between
611 | 2015 and 2020 some of the volume gain from the period before has already started thinning. The
612 | volume gain part for South Chongtar is about 10 times higher compared to North Chongtar and
613 | NN9. However, there is also considerable volume loss at higher elevations compensating about
614 | half of the gain. To put just the volume gains of these five glaciers (+0.46 km³) into perspective,
615 | the (uncompensated) volume loss of Sarpo Laggo Glacier over the full period (-0.47 km³) is the
616 | same.

618 | *Table 3: Volume changes*

620 | 5.5 Uncertainty assessment

621 | 5.5.1 Glacier length changes

622 | Uncertainties of the length changes are estimated to be in the order of one image pixel, i.e. 60 m
623 | for MSS, 30 m for TM, 15 m for OLI pan and 10 m for Sentinel-2. As frontal advances have only
624 | been measured for a change of at least 3 to 4 pixels, the given values should be well outside the
625 | uncertainty range in most cases. However, the calculated frontal advance rates for glacier NN9 and
626 | North Chongtar (Fig. 4b) show fluctuations. These can be attributed to the measurement uncertain-
627 | ties so that in reality the increase might have been smoother and more gradual. There is thus some
628 | caution to not over-interpret the details of the change rates.

630 | 5.5.2 Flow velocities

631 | The displacements measured by Landsat over the selected stable areas show median values close
632 | to the expected value of 0 m d⁻¹, with a MAD between 0.01 and 0.04 m d⁻¹, as reported in Table S2.
633 | Among the Landsat data, Landsat 7 shows the smallest standard deviation based on the MAD. For
634 | Sentinel-2, the uncertainties of the displacement on stable terrain are lower for the pairs with a
635 | time interval of approximately a year. For these pairs, the median and the MAD of the velocity are
636 | of the same order of magnitude as the Landsat results. For shorter time intervals (5 to 45 days), the
637 | Sentinel-2 velocity shows medians between 0.15 and 1.58 m d⁻¹ with a maximum MAD of 1.39 m
638 | d⁻¹. Displacement from Planet data gives the largest error with medians and MAD values ranging
639 | from 0.3 m d⁻¹ to 2.50 m d⁻¹. One pair showed a significantly higher error with a median value of
640 | 8.64 m d⁻¹ and a corresponding MAD value of 4.76 m d⁻¹, which is in a similar order of magnitude
641 | to the displacement measured in the centre line of the glacier (13.89 m d⁻¹). TSX revealed the low-
642 | est uncertainty with values of both median and MAD close to 0 m d⁻¹.

644 | 5.5.3 Elevation data

645 | The median elevation differences on stable bedrock to the reference DEM (HMA DEM) are 1.02
646 | m (SRTM), 1.03 m (SPOT 2010), -0.12 m (SPOT 2015) and 1.08 m (SPOT 2020), with standard

649 reme values, are <1.4 m for all DEM difference pairs except for the SPOT 2020-SRTM2000
650 DEM pair (2.4 +8.8 m). These are small differences and fully within the range of expected uncer-
651 tainties (after successful co-registration), considering the very steep and rugged terrain. We found
652 no indication of remaining horizontal shifts between the DEMs (this would be visible as an aspect-
653 dependent pattern in Fig. 11). The comparison of the SPOT 2015 and HMA 2015 DEM (Fig. S13)
654 shows a minor tiling effect caused by the composite nature of the HMA DEM in the upper accu-
655 mulation areas of North and South Chongtar. The mean uncertainty of the ATL06 ICESat-2 data
656 was ±5.37 m. However, we assume that ATL03 elevation uncertainties are in the order of decime-
657 tres on the relatively smooth glacier surface.

659 **5.6 Sensor inter-comparison**

660 **5.6.1 Velocities**

661 As can be seen in Fig. 7a, velocity values derived from the (optical) 15 m resolution Landsat 8
662 panchromatic band for the period July 2018 to July 2019 are about the same as from (also optical)
663 10 m resolution Sentinel-2 data for the period August 2018 to August 2019. Both lines are basical-
664 ly on top of each other. The same applies to the Landsat 8 velocities for the period September 2016
665 to October 2017 compared to Sentinel-2 values over the period November 2016 to November
666 2017. The velocities derived from the (SAR) TSX sensor over the short period April to May 2014
667 also compare well with the annual mean values from Landsat 8 over the period July 2013 to July
668 2014. In Fig. S9 we show the related velocity differences with respect to the distance along the
669 centre line for all three comparisons, revealing that they are largely within ±0.03 m d⁻¹ for the re-
670 gion between km 9 and the terminus. They are therefore as small as the stable terrain uncertainties
671 listed in Table S2. Between km 0 and 9 only a few values are available for the optical sensors and
672 these are subject to outliers. The differences are thus higher but in most cases still smaller than the
673 flow velocity.

675 The (optical) Planet cubesat images cover only the lower part of the glacier. Here, the Planet ve-
676 locity (Fig. S10) reveals the same increase/decrease pattern as the Sentinel-2 velocity profile (Fig.
677 7b). Direct comparison of the flow velocities reveals much larger differences, but compared to the
678 much higher flow velocities still only small differences (Fig. S11). These can be related to slightly
679 different time intervals, and the rapidly changing crevasse pattern at high flow velocities. On the
680 other hand, the differences are large when comparing velocities derived from Sentinel-1 (SAR)
681 with the optical Sentinel-2 (Fig. S12). The large image template sizes of 128 x 64 (450 m x 900 m)
682 for South Chongtar (tongue width 800 m) result in a strong underestimation of Sentinel-1 veloci-
683 ties with errors much greater than those reported in previous studies for larger Arctic glaciers (Paul
684 et al., 2017; Strozzi et al., 2017). The information density is also very low compared to Sentinel-2,
685 indicating that Sentinel-1 data do not reveal sufficient detail about the surge.

704 5.6.2 Elevation changes

705 Of the seven analysed elevation datasets, ICESat-2 elevation profiles show most detail compared
706 to the DEMs and is also resolving small surface features such as crevasses and séracs (Fig. S6).
707 Both the weak and the strong laser beams of ICESat-2's three beam pairs provide equally good
708 data in the snow-covered accumulation areas (Fig. S6a and b). On darker and more rugged surfac-
709 es the weak beam yields considerably fewer photon returns than the strong beam (bottom panels in
710 Fig. S6e and f).

711
712 Elevation differences between the HMA DEM and the SPOT DEM from 2015 are depicted in Fig.
713 S13. A small advance of North Chongtar and a slight elevation increase on South Chongtar within
714 the few months' time gap is visible. The latter is confirmed by the cross transects in Fig. S6c and
715 d. In contrast, the elevations of the two 2015 DEMs agree very well for the transects in the upper
716 accumulation area (top panels) and the down-wasting tongue in the main valley (bottom panels).
717 Apart from artefacts and local differences in very steep terrain, elevations of the DEMs from 2015
718 agree very well both on and off glaciers.

719
720 The elevation changes derived from the ASTER DEM time series by Hugonnet et al. (2021)
721 shown in Fig. S14 are similar to the time series we analysed from SRTM, SPOT and the HMA
722 DEMs (Fig. 11). The ASTER DEMs have more artefacts and local differences, in particular in
723 very steep terrain. In contrast, the strong spatial filtering inherent in the ASTER dataset, smooth-
724 ens artefacts and data gaps off and to some degree also details on glaciers. Locally, the ASTER
725 data set is less complete, e.g., the advance of North Chongtar is not well covered and the advance
726 of the glacier NN8 is not visible.

727
728 There are no further insights when splitting the 2000-2010 period into a 2000-2004 and 2005-2009
729 period, but the 2000 to 2019 period from ASTER (Fig. S14f) reveals the up to 40 m elevation in-
730 crease in the upper region of South Chongtar. This 'reservoir zone' seemingly stretches over the
731 entire upper glacier rather than being an isolated region. In 2019 the surge has not started, so the
732 strong elevation loss in its lower part from post-surge down-wasting of the previous surge is also
733 very prominent. Elevation gain from 2000 to 2019 is also visible for the upper part of Sarpo Lago
734 Glacier and the lower part of Moni Glacier.

The displacements measured by Landsat over the selected stable areas show median values close to the expected value of 0 m d⁻¹, with a MAD between 0.01 and 0.04 m d⁻¹, as reported in Table S2. Among the Landsat data, Landsat 7 shows the smallest standard deviation based on the MAD. For Sentinel-2, the uncertainties of the displacement on stable terrain are lower for the pairs with a time interval of approximately a year. For these pairs, the median and the MAD of the velocity are of the same order of magnitude as the Landsat results. For shorter time intervals (5 to 45 days), the Sentinel-2 velocity shows medians between 0.15 and 1.58 m d⁻¹ with a maximum MAD of 1.39 m d⁻¹. Displacement from Planet data gives the largest error with medians and MAD values ranging from 0.3 m d⁻¹ to 2.50 m d⁻¹. One pair showed a significantly higher error with a median value of 8.64 m d⁻¹ and a corresponding MAD value of 4.76 m d⁻¹, which is in a similar order of magnitude to the displacement measured in the centre line of the glacier (13.89 m d⁻¹). TSX revealed the lowest uncertainty with values of both median and MAD close to 0 m d⁻¹.

6. Discussion

6.1 Interpretation of the surges

The contrasting surge behaviour of North and South Chongtar glacier is remarkable [in that](#) the two glaciers with [probably](#) the highest (South Chongtar) and lowest (North Chongtar) flow velocities and advance rates during a surge (in the entire Karakoram) can be found side-by-side. At first glance, it seems that the sudden, short-lived surge of South Chongtar is hydrologically controlled (Alaska type), whereas the neighbouring North Chongtar surge seems thermally controlled (Svalbard type). However, as Quincey et al. (2015) noted, this simplified picture does not [work well](#) for many glacier surges in the Karakoram, which often show characteristics of both types. For example, the South Chongtar surge reached its maximum flow velocities in summer rather than winter and [its](#) drop is very slow rather than fast. [For a hydrologically controlled surge one would expect a surge start in winter \(when efficient basal hydrology switches to inefficient\) and a sudden end of the surge in summer \(when basal water can again be released efficiently\) \(e.g. Kamb et al., 1985; Raymond, 1987; Sharp, 1988\).](#) Moreover, flow velocities increased slowly, [steadily](#) and over large parts of the glacier rather than being located at a clearly localized surge front. These observations [fit](#) better [with](#) a thermally controlled surge (e.g. Fowler et al., 2001) and [imply](#) that both mechanisms apply and the surge mechanism could be named 'hybrid'.

The slow and near constant advance of North Chongtar and NN9 might not even be classified as a surge, but given that both glaciers also developed nearly all characteristics of a surge at some point, [\(e.g. a heavily crevassed surface, shear margins, strong increase in flow velocity, high frontal advance rates, mass transfer from a reservoir to a receiving zone\)](#), the former advance phase might be seen as a part of the surge. Still, from the evolution of advance rates or flow velocities alone it is nearly impossible to pin down the exact surge onset for North Chongtar. Morphological changes (heavy crevassing, shear margins) indicate that this might have happened around 2010, but considering the near linear increase of advance rates after 1996, one might assign the onset also to that year. In any case, the more or less constant advance for more than 30 years before 1996 is exceptional and only comparable to the very slow advance of Maedan Glacier in the neighbouring Panmah region that also started in the 1960s, before advance rates considerably increased in the mid-1990s and the glacier started surging (Bhambri et al. 2017; Paul, 2020). Such prolonged advances might also be a consequence of a positive mass balance that one glacier converted to a continuous advance and another one to a surge (Lv et al., 2020). At least the elevation change pattern of North Chongtar over the 2000-2020 period reveals a clear and typical redistribution of mass from a higher reservoir zone to a lower receiving zone.

FP 25 4 22 9:45 PM

Moved up [3]: to the reference DEM (HMA DEM) are 1.02 m (SRTM), 1.03 m (SPOT 2010), -0.12 m (SPOT 2015) and 1.08 m (SPOT 2020), with standard deviations of 3-15 m (Table S3). Also mean elevation differences, which are more sensitive to extreme values, are <1.4 m for all DEM difference pairs except for the SPOT 2020-SRTM2000 DEM pair (2.4 ±8.8 m). These are small differences and fully within the range of expected uncertainties (after successful co-registration), considering the very steep and rugged terrain. We found no indication of remaining horizontal shifts between the DEMs (this would be visible as an aspect-dependent pattern in Fig. 11). The comparison of the SPOT 2015 and HMA 2015 DEM (Fig.

FP 25 4 22 9:45 PM

Deleted: 5.6.3 Elevation data [2]

FP 25 4 22 9:45 PM

Moved up [4]:) shows a minor tiling effect caused by the composite nature of the HMA DEM in the upper accumulation areas of North and South Chongtar. The mean uncertainty of the ATL06 ICESat-2 data was ±5.37 m. However, we assume that ATL03 elevation uncertainties are in the order of decimetres on the relatively smooth glacier surface. .

861

862 This is different for NN9, which only shows elevation increase in its lower part over this period
863 without any measurable surface lowering higher up. This rather unique criterion for surge identifi-
864 cation fails here and would exclude the glacier from being surge type. However, a different im-
865 pression emerges when looking at the temporal evolution of advance rates and flow velocities. In
866 2016 the former increased considerably from about 40 m y⁻¹ to more than 1 km y⁻¹ and the mor-
867 phology of the surface changed from rather smooth to highly crevassed. Measurable flow veloci-
868 ties increased in 2019 from 0.2 to 0.8 m y⁻¹ and the Landsat 8 image pair from 2018 to 2019 (Fig.
869 5d) also reveals an increase. With its recent rapid advance, the glacier has now reached its former
870 1971 maximum extent and also looks the same in terms of a completely crevassed surface (Paul,
871 2020). The slow advance might have resulted from a positive mass balance but could also be a
872 thermally controlled surge. However, the recent increase in advance rates could also be due to a
873 hydrologically controlled surge and/or due to the steep slope and dynamic effects. Compared to
874 North Chongtar, the switch from advance to surge occurred much more sudden.

875

876 For South Chongtar the situation is clearer as its rapid advance and more than 100-fold increase in
877 flow velocities (from 0.2 to more than 25 m/d) is typical for a hydrologically controlled surge with
878 increasing basal water pressure. We assume that its thin lowest part was frozen to the bed (e.g.
879 Obu et al., 2019), effectively blocking water release for some time. The interesting points of the
880 current surge are: (a) the gradual increase of flow velocities in the region above its fixed terminus
881 (at [km 13.5](#)), (b) the extreme velocity increase from July to September 2020, (c) the high maxi-
882 mum velocities of 30 m d⁻¹, (d) the location of the maximum away from the centre [line](#), and (e) the
883 more or less constantly high flow velocities over large parts of its length from January to May
884 2021. The latter is responsible for the ongoing mass transport and advance of the terminus and im-
885 plies that basically the entire glacier was activated by the surge. As mentioned above, points (a)
886 and (e) are more typical for thermally controlled surges so with both characteristics this surge can
887 be classified as hybrid. That velocities increase from the centre to the boundary of a glacier (Fig.
888 9) is likely rather unique. We assume this is caused by the surrounding topography, i.e. the change
889 of flow direction from northwest to north imposed by the mountain walls. The centre of the ad-
890 vancing terminus collided with the southern rock wall and was then diverted to a different direc-
891 tion. As the glacier was likely sliding over its full width, the resistance at the boundaries was likely
892 limited.

893

894 Maximum surface flow velocities of 30 m d⁻¹ are only visible with Planet and to the edge of the
895 glacier (Fig. 9), Sentinel-2 values peak at 27 m d⁻¹. This is likely due to the higher resolution of
896 Planet compared to Sentinel-2 and hence to the smaller region used for spatial averaging. Also the
897 shorter time period considered (3 days) might play a role. Whereas high flow velocities of about
898 15 m d⁻¹ have been reported previously (Quincey et al., 2015; Paul et al., 2017; Bhambri et al.,

FP 25 4 22 9:45 PM

Deleted: km

900 2020), values above 25 m d⁻¹ are only rarely observed in the Karakoram (Rashid et al., 2020). The
901 latter study reports values near 50 m d⁻¹ for the last surge of Shispar Glacier (derived from 3 m
902 Planet data), but the flow fields look a bit ‘bumpy’ and image processing artefacts might have con-
903 tributed to the high values. We assume that the rapid increase in flow velocities during Ju-
904 ly/August was due to additional lubrication from summer surface melt water.

905

906 In principle, a surge simply moves mass downstream implying that the net volume change should
907 be about zero. However, if surges take place over very long periods (>5 years) there will also be a
908 signal from the usual ablation and accumulation. Moreover, for DEMs derived from optical sen-
909 sors problems in snow covered or steep terrain (shadow) exists that might create data gaps in the
910 region where the mass has been removed (or where mass gain took place before a surge). Both
911 effects can create biases leading to over- or underestimation of calculated volume changes. These
912 apply also to the changes calculated over ten-year periods and the SPOT DEM from 2010 that had
913 data voids in the steep upper regions of some glaciers. In consequence, volume changes calculated
914 with this DEM are incomplete and need to be interpreted with care. However, as both positive and
915 negative changes take place in regions of increased uncertainty, the net effect is likely small.

916

917 **6.2** Uncertainties

918 The one-pixel uncertainty in deriving terminus positions and length changes translates into an un-
919 certainty of the calculated advance rates. How large the uncertainties are, depends on the sensor
920 resolution and the time period between two measurements. It is assumed that at least a part of the
921 short-term variations in the advance rates of NN9 and North Chongtar are due to these uncertain-
922 ties rather than real variability.

923

924 With the exception of the Planet data, the uncertainty of the velocity measured over stable terrain
925 by all sensors is one or two orders of magnitude smaller than the maximum displacement observed
926 on the glacier along the centreline, even for the two small glaciers NN9 and North Chongtar. For
927 them, cloud cover has been identified as a major challenge for optical sensors. In fact, the selection
928 of the satellite pair prioritized the reduction of cloud cover on South Chongtar rather than NN9 and
929 North Chongtar, which were rarely cloud-free. Hence, it is not only spatial resolution that is re-
930 sponsible for data limitations.

931

932 In general, the uncertainties of glacier flow velocity measurements are mainly related to co-
933 registration accuracy, orthorectification, the time interval between image pairs, surface conditions
934 (shadow, snow, etc.) and the spatial resolution of the images. The larger the time window between
935 two pairs, the smaller the uncertainty of the measured velocity. Despite the higher resolution, the
936 uncertainty is higher for Planet than for Sentinel-2. For Sentinel-2, the orthorectification error is
937 minimized because the imagery comes from the same relative orbit (Kääb et al., 2016). On the

FP 25 4 22 9:45 PM
Moved (insertion) [5]

FP 25 4 22 9:45 PM
Moved (insertion) [6]

938 contrary, we have different orbital paths between Planet image pairs and therefore further geomet-
939 ric corrections may be needed to minimize this error, as also suggested by Kääh et al. (2017) and
940 Millan et al. (2019). Also the very small stable terrain uncertainties of TSX are likely due to the
941 accurate co-registration of the image pairs.

942
943 The observed elevation changes exceed the DEM elevation uncertainties by an order of magnitude
944 or more, which makes our elevation change analyses very robust. For volume change studies, data
945 gaps in the DEMs and remaining blunders/bias from clouds or other sources cause greater uncer-
946 tainties than the elevation uncertainties themselves (McNabb et al. 2019). Data gaps occur, how-
947 ever, mostly in the accumulation areas due to reduced contrast over snow, more persistent cloud
948 cover and steeper terrain. Moreover, surface elevation tends to change much less here than it is the
949 case for the tongues, and uncertainties might become as large as the changes. The elevation accu-
950 racy of the ICESat-2 ATL03 product is clearly superior to all DEMs analysed within this study.

952 **6.3 Sensor capabilities and limits**

953 The sensor intercomparison revealed a very good agreement between the velocity data derived
954 from both TSX StripMap mode and Sentinel-2 with Landsat 8 (Fig. 7a), as well as between Senti-
955 nel-2 and Planet (Fig. [S11](#)). This confirms that all three optical sensors can be used to derive the
956 temporal evolution of flow velocities – cloud cover, snow conditions and cast shadow permitting.
957 The key point is the choice of the temporal baseline of image pairs as a function of glacier surface
958 changes, sensor resolution and the targeted velocity field. At 20 m d^{-1} a 5-day interval is equivalent
959 to a change by 10 pixels with Sentinel-2 and 20 pixels with Planet over 3 days (assuming a 3 m
960 resolution). At 0.1 m d^{-1} the displacement is about 35 m (3 Sentinel-2 pixels) after a year, which is
961 at the lower end of what is detectable with offset-tracking.

962
963 For SAR data the typical limitations are layover/foreshortening, radar shadow, SAR penetration
964 and decorrelation. Actually, none of these created problems for the TSX and Sentinel-1 image
965 pairs used here. However, Sentinel-1 performed poorly even on the largest glacier, South Chong-
966 tar. This was mostly due to the fact that this glacier has a long and narrow tongue (width less than
967 800 m) situated between steep mountain flanks. Because of the relatively large size needed for the
968 matching window (Fig. S4), too many non-moving off-glacier pixels are included affecting the
969 velocity retrieval considerably (Fig. [S12](#)). Also, the large and fast surface changes on the rapidly
970 surging glacier might have changed the backscatter patterns too much to be tracked over time
971 (Strozzi et al., 2017). The minimum width of a glacier to be reliably monitored with Sentinel-1 in
972 the Himalayas is likely around 2 km. On the contrary, TSX yielded dense and consistent velocity
973 values for all three glaciers (pre-surge-phase). As it seems, the map in Fig. 5b captures nicely the
974 flow acceleration of North Chongtar in 2012, which decreased afterwards (Fig. 6b). The much
975 noisier values from Landsat 8 in this figure (compared to Sentinel-2 and TSX) revealed that the 15

986 m resolution of the Landsat panchromatic band is seemingly insufficient to track displacements
987 precisely. Note, though, that these comparisons are not [strict](#) as the sensors have different resolu-
988 tions, and the datasets cover different phases of the surges and thus different surface conditions.

989
990 The compared DEMs are of similar quality over glaciers, but the SPOT 2010 DEM used by
991 Gardelle et al. (2013) suffered from strong artefacts at steep slopes. The elevation values of the
992 SPOT 2015 and HMA DEM (which is also from 2015 in this region) are basically identical apart
993 from individual raster cells, [\(e.g. showing the advancing terminus of North Chongtar\)](#). So elevation
994 changes from 2000 (SRTM) to 2015 (HMA DEM) can also be derived from freely available
995 DEMs. The SPOT 2020 DEM is of superb quality but the raw image pair had to be purchased. For
996 a study looking at specific glaciers this is certainly worthwhile, but does typically hamper larger
997 regions to be covered.

998
999 The surface elevation detail and accuracy of the freely available ICESat-2 ATL03 photon data sur-
1000 passes all other datasets, including the SPOT 2020 DEM (Fig. S6). When combined with one or
1001 several DEMs, the higher temporal resolution provides additional information on how the eleva-
1002 tion changed in-between DEM time stamps. This may be very useful for slower changes or to fur-
1003 ther constrain the onset/end of a rapid change, such as a surge. However, ICESat-2 only provides
1004 elevation profiles with varying locations, which makes this data type more demanding to analyse.
1005 The footprints of the ICESat-2 ATL06 time series alone are too sparse to derive any useful trends
1006 in glacier surface elevation.

1007
1008 The DEM time series from ASTER images (Fig. [S14](#)) derived by Hugonnet et al. (2021) shows the
1009 same trends as from the DEMs used here. They provide further information over the 2000–2005
1010 and 2005–2010 periods, but miss the surge of South Chongtar as they end in 2019. On the other
1011 hand, they cover a much larger area and clearly reveal the increase in surface elevation of South
1012 Chongtar over the full 2000-2019 period. The coverage of the smaller glaciers is noisier with AS-
1013 TER than with the DEMs we have used and locally values are missing, but the temporal evolution
1014 over several larger glaciers can be well followed. Deriving further DEMs from future ASTER ste-
1015 reo scenes might thus help to determine total volume changes after all surges have come to an end,
1016 including the [not yet](#) visible volume loss in the reservoir zone of NN9.

Moved up [5]: Uncertainties .

FP 25 4 22 9:45 PM

Moved up [6]: in the advance rates of NN9 and North Chongtar are due to these uncertainties rather than real variability. .

With the exception of the Planet data, the uncertainty of the velocity measured over stable terrain by all sensors is one or two orders of magnitude smaller than the maximum displacement observed on the glacier along the centreline, even for the two small glaciers NN9 and North Chongtar. For them, cloud cover has been identified as a major challenge for optical sensors. In fact, the selection of the satellite pair prioritized the reduction of cloud cover on South Chongtar rather than NN9 and North Chongtar, which were rarely cloud-free. Hence, it is not only spatial resolution that is responsible for data limitations. .

In general, the uncertainties of glacier flow velocity measurements are mainly related to co-registration accuracy, orthorectification, the time interval between image pairs, surface conditions (shadow, snow, etc.) and the spatial resolution of the images. The larger the time window between two pairs, the smaller the uncertainty of the measured velocity. Despite the higher resolution, the uncertainty is higher for Planet than for Sentinel-2. For Sentinel-2, the orthorectification error is minimized because the imagery comes from the same relative orbit (Kääb et al., 2016). On the contrary, we have different orbital paths between Planet image pairs and therefore further geometric corrections may be needed to minimize this error, as also suggested by Kääb et al. (2017) and Millan et al. (2019). Also the very small stable terrain uncertainties of TSX are likely due to the accurate co-registration of the image pairs. .

The observed elevation changes exceed the DEM elevation uncertainties by an order of magnitude or more, which makes our elevation change analyses very robust. For volume change studies, data gaps in the DEMs and remaining blunders/bias from clouds or other sources cause greater uncertainties than the elevation uncertainties themselves (McNabb et al. 2019). Data gaps occur, however, m

7. Conclusions

We have identified and presented an analysis of three glacier surges in the central Karakoram, all taking place in the same [small](#) region but with very different characteristics and possibly forcing mechanisms. South Chongtar showed advance rates of more than 10 km y⁻¹, velocities up to 30 m d⁻¹ and surface elevations rose by 200 m, [all within a surge duration of about 2-3 years](#). The three times smaller [and neighbouring](#) North Chongtar [Glacier had](#) a slow and almost-linear increase of advance rates (up to 500 m y⁻¹) [over a period of almost 50 years](#), flow velocities below 1 m d⁻¹ and elevation increases of up to 100 m. [A more active phase from 2010 to 2015 was followed by a continuation of its slow advance](#). The even smaller glacier NN9 changed from a slow advance to a full surge within a year, reaching advance rates higher than 1 km y⁻¹, but showing the typical surface lowering higher up only recently. Total length changes reached between 2 and 2.7 km for the three glaciers and the size of NN9 changed by more than 20%. For South Chongtar, maximum flow velocities are found near its southern boundary rather than in the centre.

At first glance, the surge of South Chongtar clearly resembles the classical Alaska type surge (hydrologically controlled), whereas North Chongtar and NN9 better fit to the Svalbard type (thermally controlled). However, the summer onset and slow velocity decay of the South Chongtar surge and the sudden change in frontal advance rates of NN9 hint to the respective other type, resulting in a change of characteristics. North Chongtar has not changed type but surge onset is difficult to determine as advance rates increased linearly, morphological changes developed slowly and a 50-year advance might also be called a surge. When the definition of a surge is stricter, we would assign the surge onset of NN9, North and South Chongtar to 2017, 2005-2010 and August 2019, respectively. We speculate that the thin, lower part of South Chongtar was cold ice frozen to the bed, reducing possibilities for the terminus to advance and causing basal pressure to strongly increase.

The sensor intercomparison revealed that Landsat 8 and Sentinel-2 are difficult to be used jointly for determination of geometric changes as their geolocation differs (>30 m). Flow velocities agreed well across sensors for South Chongtar, except for Sentinel-1 that had problems due to its narrow tongue (800 m). However, the backscatter intensity images provided a time-series of surge evolution at a near constant interval that is undisturbed by clouds. At the two smaller glaciers NN9 and North Chongtar, the optical sensors still provided reasonable and consistent flow velocities, but limits due to spatial resolution and cloud cover became visible (more noise). The TerraSAR-X acquisitions in StripMap mode revealed by far the best results and depicted the surge of North Chongtar accurately.

After proper co-registration, all DEMs provided useful results to track elevation and volume changes, independent of glacier size. The two SPOT DEMs from 2010 and 2015 suffered from artefacts at steep slopes, but the latter compared very well to the HMA-DEM. The high-resolution SPOT6 DEM from Oct 2020 had impressive quality and allowed an accurate calculation of the volume change of all glaciers up to this point in time. The very precise ICESat-2 elevation profiles provided additional information in space (glacier surface details) and time (between the DEMs) that matched well to the other datasets. The ASTER DEM time series missed detecting local changes of smaller glaciers, but provided a larger overview and complementary information on cumulative elevation changes shortly before the surge of South Chongtar started.

All three glaciers are still advancing and South Chongtar and NN9 are now colliding. The bulldozing of the South Chongtar terminus into the down-wasting ice of Sarpo Laggo Glacier is already creating interesting morphological changes. North Chongtar might again reach the floor of the main valley as in the 1930s, but this could take some more years. We conclude that the past and further evolution of these and other glacier surges can be well observed from satellite data, at best by combing all available datasets.

Supplement

The supplement related to this article is available on-line at: TBD

Author contributions

F.P. detected the surges, lead the writing and analysed changes in extent and morphology. L.P. contributed equally, derived the optical velocity data and prepared all related tables and figures; D.T. derived and combined the elevation change data. All authors contributed to the writing, discussion and editing of the text.

Code and data availability

Data processing has been performed using freely available (e.g. CIAS, MicMac, geopandas/rasterio/shapely) or in-house software (for SAR offset-tracking). [In addition](#), most of the datasets used here are freely available (e.g. Landsat, Sentinel-1/-2, ICESat-2, SRTM and HMA DEMs, glacier outlines) [or can be obtained with a quota \(Planet\)](#). TerraSAR-X data [were](#) ordered from DLR, and the SPOT2020 DEM [was purchased from](#) Airbus. The SPOT DEMs from 2010 and 2015 were provided by E. Berthier.

Competing interests

The authors declare that they have no conflict of interest.

2039 | **Supplemental [animation](#)**

2040

2041 **Time series from Sentinel-1**

2042 Radar satellites can 'see' through clouds and Sentinel-1 offers frequent and systematic coverage in
2043 areas prone to monsoon clouds as the Himalayas. Despite radar speckle and 74 m x 56 m spatial
2044 resolution of 20x4 multi-looked products, the rapid advance of Chongtar glacier since July 2020
2045 can be clearly observed in Sentinel-1 backscattering intensity images (Figure SA). Changes in
2046 backscattering intensity at the glacier surface are mostly due to a change in the physical properties
2047 of the ice, e.g. liquid water resulting from melting reduces intensity considerably. The animation
2048 of 12-days Sentinel-1 backscattering intensity images shows the sudden advance of South Chong-
2049 tar glacier in Summer 2020. The file is named 'chongtar_surge_anim.gif'.

2050
