Abstract. We present repeated radio-echo sounding (RES, 5 MHz) on a profile grid over the Eastern Skaftá Cauldron (ESC) in Vatnajökull ice cap, Iceland. The ESC is a ~3 km wide and 50–150 m deep ice cauldron created and maintained by subglacial geothermal activity of ~1 GW. Beneath the cauldron and 200–400 m thick ice, water accumulates in a subglacial lake and is released semi-regularly in jökulhlaups. The RES record consists of annual surveys with 200–400 m between profiles in early ~~summers~~summer of 2014–2020. Comparison of the RES surveys (2D migrated profiles) reveals variable lake area (0.5–4.1 km²) and enables traced reflections from the lake roof to be distinguished from bedrock reflections. This allows construction of a digital elevation model (DEM) of the bedrock in the area, further constrained by two borehole measurements at the cauldron centre. It also allows creation of lake thickness maps and an estimate of lake volume at the time of each survey, which we compare with lowering patterns and released water volumes obtained from surface DEMs obtained before and after jökulhlaups. The estimated lake volume is 250x10⁶ m³ in June 2015 but 320±20x10⁶ m³ drained from the ~~cauldron~~ESC in October 2015. In June 2018, RES profiles ~~reveal~~revealed a lake volume of 185x10⁶ m³ while 220±30x10⁶ m³ ~~was~~were released in a jökulhlaup in August 2018. Considering the water accumulation over the periods between RES surveys and jökulhlaups, this indicates 10–20% uncertainty in the RES-derived volumes at times when significant jökulhlaups may be expected.

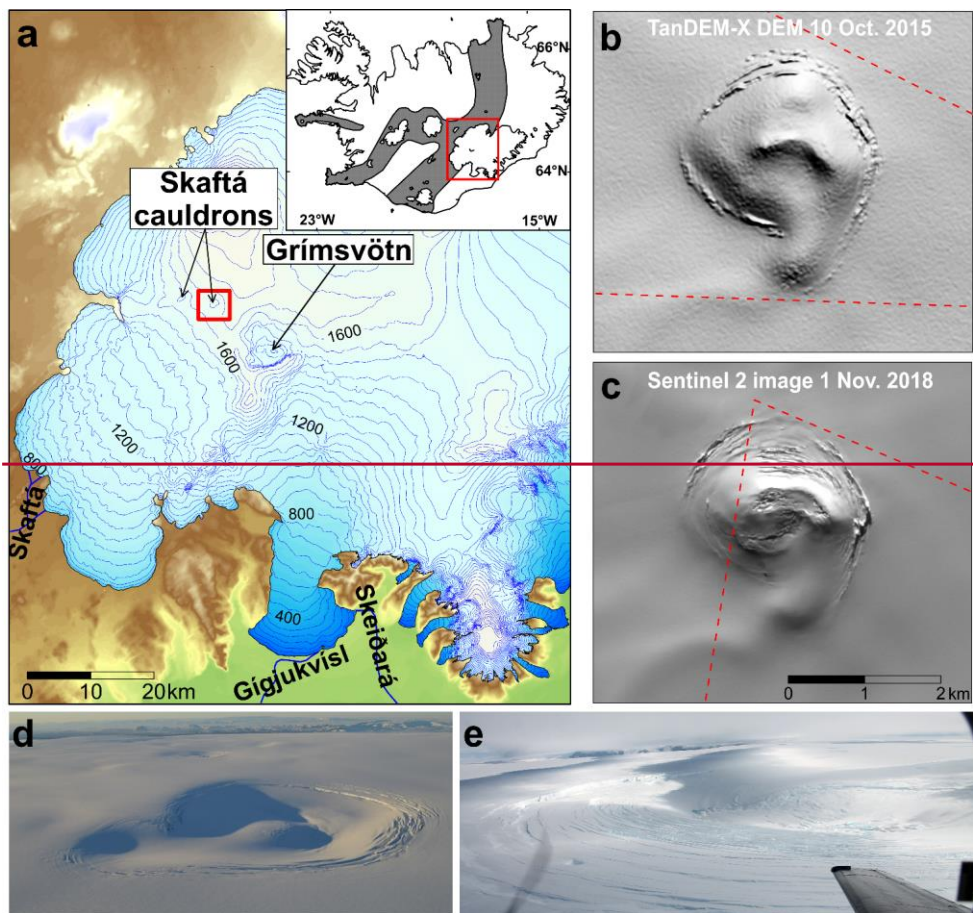

1 Introduction

Subglacial lakes ~~are known in~~have been directly and indirectly observed beneath both temperate and cold-based glaciers. ~~Floods originating~~The sudden release of water from subglacial~~such~~ lakes can lead to floods, commonly referred to as jökulhlaups ~~are well known and, which can be~~ of variable magnitude. In warm-bedded glaciers jökulhlaups are known to cause widespread and a manifold increase in basal sliding over periods of days (e.g. Einarsson et al., 2016), while a persistent leakage from such a lake caused significant deceleration of a glacier over a period of years (Magnússon et al., 2010). In Antarctica, water originating from subglacial lakes has been identified as a key cause of persistent fast-flow features (Bell et al., 2007; Fricker et al., 2007; Langley et al., 2011) as well as the cause of transient acceleration (Stearns et al., 2008).

~~Many~~The detection of subglacial lakes ~~have~~has been ~~identified based on~~achieved using a combination of radio-echo sounding (RES) ~~data and satellite remote sensing, but routine monitoring of such lakes remains a difficult task.~~ The first such RES observation was made more than 50 years ago (Robin et al., 1970), when RES data, acquired near the centre of East Antarctica, revealed a ~10 km long unusually flat subglacial surface with high reflectivity attributed to a “thick ~~layer of water~~ ~~layer~~ beneath the ice”. Since then, RES has been used to identify hundreds of subglacial lakes. ~~However, many subglacial lakes actively drain and fill, and as a result are difficult to distinguish in RES data (Carter et al., 2007; Siegert et al., 2014, most of them beneath the Antarctic ice sheet.), hence SAR interferometry and repeatedrepeat altimeter surveys have in the past two decades revealed more than hundred been used to identify hundreds of~~ areas of surface elevation changes within Antarctica that are associated with ~~draining or filling of active~~ subglacial lakes in Antarctica (e.g. Gray et al., 2005; Smith et al., 2009), ~~showing the dynamic nature of subglacial water systems. Many of these active lakes are, however, hard to detect from RES data and do not reveal a flat subglacial surface nor clear changes in reflectivity at the glacier bed (Carter et al., 2007; Siegert et al., 2014). In some areas and particularly in Iceland, jökulhlaups originating from subglacial lakes are real natural hazards. Since the settlement of Iceland they have threatened the lives of people and livestock and repeatedly ruined farms, fields and vegetated areas. In the past century roads and bridges have been destroyed. This may explain why the recognition and research of subglacial lakes beneath Icelandic ice caps dates farther back than elsewhere (Thorarinsson and Sigurðsson, 1947; Thorarinsson, 1957). The subglacial lakes beneath the Icelandic ice caps owe their existence to localized geothermal activity beneath the glaciers. The basal melting produces a depression in the glacier surface often referred to as ice cauldrons. This causes a low in the hydrostatic potential, which facilitates subglacial accumulation of meltwater both from the glacier surface and bed (Björnsson, 1988).~~

~~In Iceland, subglacial lake drainage events that lead to jökulhlaups have been documented since the early 1900s (Thorarinsson and Sigurðsson, 1947; Thorarinsson, 1957) and the floods are known to cause widespread destruction of farms and infrastructure, as well as threatening the lives of people and livestock. The three largest subglacial lakes in Iceland are located beneath the western part of the Vatnajökull ice cap (Fig. 1); Grímsvötn and the lakes beneath the two Skaftá cauldrons (denoted as the Eastern Skaftá Cauldron (ESC) and the Western cauldron)-Skaftá Cauldron (WSC). These lakes are formed through localized geothermal activity, where enhanced basal melting forms topographical depressions on the glacier surface (ice cauldrons), creating a low in the hydrostatic potential and promotes water accumulation from both the glacier surface and the bed (Björnsson, 1988). Grímsvötn has been known for centuries as a lake within Vatnajökull andas the source of large jökulhlaups draining from Skeiðarárjökull outlet glacier in S-Vatnajökull, although the exact location was not well known until identified in an expedition in 1919 (Wadell, 1920). Accounts describing jökulhlaups in the river Skaftá, probably draining from the Skaftá cauldrons, date at back to the first half of the 20th century (Björnsson, 1976; Guðmundsson et al., 2018). The first direct observation of the Eastern Skaftá cauldron (ESC) as a depression in the glacier surfaceESC is a photograph taken from an airplane in 1938. Aerial photographs taken by the U.S. Army Map Service in 1945 and 1946 indicate that the Western Skaftá cauldron (WSC)WSC did not exist at that time while ESC was much smaller than at present. The first known photographs showing the WSC were taken in 1960 (Guðmundsson et al., 2018).~~

The ~~amount~~ geothermal power beneath Grímsvötn has been estimated from the volume of water ~~draining from these areas in discharged through jökulhlaups has, combined with information on and~~ surface mass balance, ~~been used and~~ is estimated to estimate the power of the geothermal areas beneath Grímsvötn and the Skaftá cauldrons ~~be~~ approximately 1500–2000 MW (Björnsson, 1988; Björnsson and Guðmundsson, 1993; Reynolds et al., 2018). The same approach results in similar power for ESC and WSC combined (Guðmundsson et al., 2018; Reynolds et al., 2018; Jóhannesson et al., 2020). These estimates result in a geothermal power of 1500–2000 MW for Grímsvötn and similar power for the two Skaftá cauldrons combined,) making these regions some of the most powerful geothermal areas in Iceland. Large-scale melting by volcanic eruptions caused the most recent major jökulhlaups draining from Grímsvötn in 1938 and 1996, ~~resulting which resulted in release of respectively~~ 4.7 km³ and 3.4 km³ of water being released, respectively (Guðmundsson et al., 1995; Björnsson, 2002). In comparison, the largest jökulhlaups from the Skaftá cauldrons are an order of magnitude smaller (Zóphóníasson, 2002; Egilsson et al., 2018).

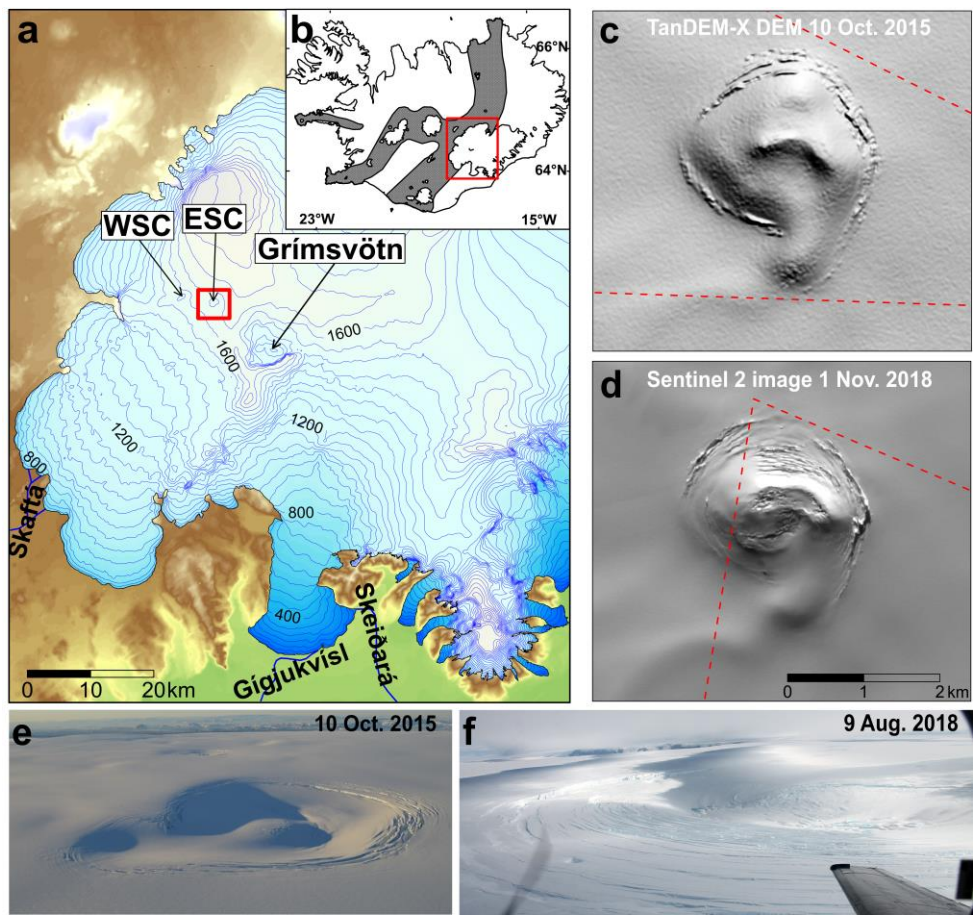

Figure 1 **a:** The western part of Vatnajökull ice cap (red box in **b**), situated within the volcanic zones of Iceland (grey areas on inset in **b**) and the locations of the Grímsvötn subglacial lake and the lakes beneath the Skaftá cauldrons: (WSC and ESC). Jökulhlaups from the Skaftá cauldrons drain to the river Skaftá. Jökulhlaups from Grímsvötn drained until 2009 into the river Skeiðará (approximate position around the year 2000) and since then into the river Gígjukvísl. **b:** TanDEM-X DEM of the Eastern Skaftá cauldron (ESC) obtained a week after the jökulhlaup in 2015 represented as shaded relief (DEM location shown with red square in **a**). **c:** Sentinel 2 optical image of the same area as in **b** showing ESC almost ~3 months after the jökulhlaup in 2018 of. **d-e-f:** Photographs taken about 1 week after the 2015 (**d**) by Benedikt Ófeigsson and 2018 (**e**) by Magnús T. Guðmundsson jökulhlaups. The viewing angles are indicated with dashed red lines in **b** and **c**.

The setting at Grímsvötn is unique for subglacial lakes in Iceland, the lake being located inside a triple composite caldera forming the centre of the highly active Grímsvötn central volcano (Guðmundsson et al., 2013a). Most of the ice melting, volcanic and geothermal, takes place near the caldera rims while the main water volume is stored near the centre of the main caldera. In June 1987, low water ~~level-in-levels within the~~ Grímsvötn ~~nine-months-after-subglacial lake due to~~ a jökulhlaup ~~made it possible to map~~ nine months previously enabled mapping of the ~~lake bed~~ lakebed with RES and ~~additional~~ active seismic observations, ~~possible~~ (Björnsson, 1988; Guðmundsson, 1989). ~~This, along~~ Taken together with knowledge ~~about~~ of the thickness of the ~~lake's glacier cover, allowed monitoring overlying ice, the volume~~ of the subglacial lake ~~volume can be inferred~~ by measuring the surface elevation of the lake's glacier cover near its centre (Björnsson, 1988; Guðmundsson et al., 1995).

~~Such straightforward estimates leading to reasonably accurate results are generally not possible for lakes. However, there is not a clear direct relationship between surface elevation within an ice cauldron and the volume of the subglacial lake beneath ice cauldrons, including the Skaftá cauldrons. The interaction between intense, Intense melting at the bed and strongly converging ice flow, particularly leads to substantial spatial and temporal variations in glacier thickness above the lake, in particular when a cauldron is steep and deep shortly after jökulhlaups, leads to great temporal and spatial variations in the glacier thickness above the lake. Hence there is not be a clear relationship between. Despite these drawbacks, the surface elevation within an ice cauldron and the volume of the lake beneath.~~

~~Monitoring the water released through jökulhlaups can be quantified by mapping surface elevation of an ice cauldron provides useful information on the cauldron's behaviour, despite the lack of quantitative results regarding the lake's volume. This particularly applies to studies of jökulhlaups causing significant deepening of the cauldrons as mapping of the surface lowering can be used to measure the volume of the released flood water. Regular measurements of the ice cauldrons during jökulhlaups (Guðmundsson et al., 2018). The surface elevation near the centres of the Skaftá cauldrons have been carried out regularly monitored since the late 1990's/1990s using GNSS, airborne radar altimetry and additional Digital Elevation Models (DEMs) from various sources (Guðmundsson et al., 2018; http://jardvis.hi.is/skaftarkatlar_yfirbord_og_vatnsstada). The elevation has been measured with ground-based GNSS measurements, repeated radar altimetry profiling from an airplane (Guðmundsson et al., 2007) and from sporadic continuous digital elevation models (DEMs) obtained from various remote sensing data.~~

In Iceland, ~~the~~ attempts to survey water accumulation below ice cauldrons using changes in the elevation of reflective subglacial surfaces from low frequency (5 MHz) RES data, were motivated by a swift, unexpected jökulhlaup from the cauldrons of Mýrdalsjökull ice cap, S-Iceland, in July 2011 (Galeczka et al., 2014). ~~This particular jökulhlaup destroyed the~~ bridge over the river Múlakvísl, cutting the road connection along the south coast of Iceland for more than a week. ~~The~~ Subsequently, RES data have been acquired up to twice a year over the same RES profiles across survey lines covering the Mýrdalsjökull cauldrons ~~have been repeated, following the same path as accurately as possible, once or twice a year since May 2012, with the aim of detecting if unusual/abnormal water accumulation takes place beneath the cauldron glacier bed~~ (Magnússon et al., 2017; in review press). This ~~same RES survey novel approach to monitoring subglacial lake activity has~~ now been ~~carried out~~ applied to the ESC, where RES data has been acquired annually ~~over ESC~~ since June 2014. At that time

jökulhlaups had not been released from ESC for 4 years while the typical interval between jökulhlaups is 2–3 years (Guðmundsson et al., 2018). The unusually long pause as well as the insignificant rise in cauldronESC surface elevation since summer 2011 ~~were curious, motivating~~ motivated the acquisition of annual RES survey at ESC data.

In this paper, the results of the annual RES study on surveys over the ESC are presented. ~~This includes~~ Firstly, the RES data are used to derive a DEM of the glacier (and lake)-bedrock beneath the cauldroncauldrons and the lake as well as an annual estimatecreating a record of the area, volume and shape of the lake every year in 2014–2020. ~~We also~~ Secondly, we present a unique comparison of the subglacial lake volume and shape in spring 2015 and 2018 with elevation changes within the cauldron during two unusually large and destructive jökulhlaups, in autumn 2015 and in summer 2018, with a maximum discharge of $\sim 3000 \text{ m}^3 \text{ s}^{-1}$ and $\sim 2000 \text{ m}^3 \text{ s}^{-1}$, respectively (Jónsson et al., 2018 and unpublished data of the Icelandic Meteorological Office (IMO)). This givesprovides a newunique insight into how the rapid emptying (days)drainage of a subglacial lake, with fairly well of known geometry, is reflected as influences elevation changes at the surface of the 200–400 m thick ice cover. The good agreement between. Finally, the lake volumes obtained fromof the RES surveys2015 and 2018 jökulhlaups, deduced from the observed surface lowering during the consequent jökulhlaup, as demonstrated below, shows these events, serve as independent validation of the RES results to demonstrate the applicability of repeat RES surveys as a tool to monitorfor monitoring water accumulation in the lake, and the potential hazard of jökulhlaups from the Eastern Skaftá CauldronESC.

2 Data and Methods

2.1 Radar data

The RES data were obtained in early June or late May each year from 2014 to 2020 during the annual field trips of the Iceland Glaciological Society on Vatnajökull. The original profile grid over ESC first measured in 2014 consists of two sets of parallel profiles (400–500 m between profiles), perpendicular to each other (Fig. 2a). This profile grid has since then been re-measured as accurately as possible every year (Fig. 2–4). Some parts of the profiles could not be measured in 2016 due to large crevasses formed during the 2015 jökulhlaup (Fig. 1b). Other parts of the survey profiles in 2017 and 2018 were defect due to artefacts in the survey caused by a supraglacial lake formed within the cauldron in the summer of 2016 and covered with snow the following winter (Fig. 5). Between the 2019 and the 2020 surveys, an englacial water body was probably formed tens of meters below the glacier surface, affecting a substantial part of the 2020 RES data with similar artefacts as in 2017 and 2018 (Fig. 2h). The surroundings of the Skaftá cauldrons were specifically measured in 2017 and 2019. The density of the profile grid within the cauldrons was doubled (200–250 m between profiles) in 2018 (Fig. 4), perpendicular to each other (Fig. 2b). This profile grid has since then been re-measured every year (Fig. 2–4) following a pre-planned track in the navigation instrument of the snowmobile. This typically results in <10 m planar offsets between profiles from individual years, except when profiles are intersected by new crevasse formations. Dates and specific remarks concerning individual RES surveys are given in Table 1.

Table 1: Dates and specific remarks on individual RES surveys.

<u>RES survey date</u>	<u>Survey remarks</u>
<u>5 June 2014</u>	<u>Original RES survey lines (400–500 m between profiles)</u>
<u>3 June 2015</u>	<u>Repeat survey lines from 2014</u>
<u>9 June 2016</u>	<u>Large crevasses formed in the 2015 jökulhlaup prevented survey of some of the RES profiles</u>
<u>7 June 2017</u>	<u>Some RES profiles defective due to supraglacial lake, formed in summer 2016, covered with snow the following winter (Fig. 5). ESC surroundings surveyed.</u>
<u>4 June 2018</u>	<u>Supraglacial lake still causing problems. The density of the survey lines was doubled (200–250 m between profiles)</u>
<u>31 May 2019</u>	<u>Subglacial lake at minimum size due to the jökulhlaup in 2018. Despite crevasses most of the survey lines were measured.</u>
<u>3 June 2020</u>	<u>An englacial water body probably tens of meters below the surface, affecting the RES measurements</u>

The RES data were acquired, following similar practice as for most RES surveys of Icelandic glaciers (e.g. using standard surveying practices developed previously in Iceland (e.g. Björnsson and Pálsson, 2020; Magnússon et al., in review), by towing with a snowmobile a low frequency in press). The radar transmitter (5-MHz centre frequency) and a receiver unit were placed on separate two sledges, separated by distance, a , (35–45 m apart, with corresponding antennae varying between surveys), in a single line. The snowmobile was equipped with a Differential Global Navigation Satellite System (DGNSS) receiver. The receivers used in this study were developed and towed along the ice surface using a snowmobile. The low radar frequency applied (5 MHz centre frequency) generally secures clear backscatter from the glacier bed beneath 200–700 m of temperate ice found at ESC and nearby. During a RES survey, the radar transmits a pulse, which travels as a direct wave along the glacier surface between transmitter and receiver triggering the recording of the receiver (developed by Blue System Integration Ltd. (., see Mingo and Flowers, 2010). The raw RES data are backscatter images where the x-axis corresponds to the number of the RES survey (256 or 512 stacked measurements), as well as penetrating into the glacier. The y-axis penetrated signal is the travel time of received backscattered transmission from englacial reflectors or the bed up to the receiver at the surface, which records the strength of the both the direct and backscattered signal. The signal strength is recorded as a function of detection time relative to the triggering time of the measurement but receiver measurement is triggered by the direct wave propagating along the surface from the transmitter. The and adding to it the traveling time of the direct wave between transmitter and receiver (using $c_{\text{air}}=3.0 \times 10^8 \text{ m s}^{-1}$) yields the two way travel time of the backscattered signals. Each recording corresponds to 256 or 512 RES measurements stacked to increase signal to noise ratio. The sounding plus processing time of the stacked measurements of each recording is $\sim 1 \text{ s}$. The strong direct wave from the transmitter is estimated as the average wave form measured with the RES over several km long segments. This is then subsequently subtracted from the corresponding RES recordings. The remaining backscatter is amplified as a function of travel time in order to have the backscatter strength roughly independent of the reflectors depth.

175 The snowmobile towing the radar was equipped with a Differential Global Navigation Satellite System (DGNSS) receiver. A
centre position, **M**, between transmitter and receiver ~~for~~is assigned to each RES ~~survey was~~recording. It is derived from the
GNSS timestamp obtained by the receiver unit for each RES sounding, and the corresponding position of the DGNSS on the
snowmobile projected back along the DGNSS profile by a distance corresponding to ~~the~~ half the antenna separation ($a/2$) plus
 b , the distance from the RES receiver sledge to the snowmobile (~20 m). Both a and b were measured with tapeline for each
180 survey and assumed fixed for each survey date. When surveying profiles without taking sharp turns the horizontal accuracy of
M is expected to be <3 m but errors are mainly due to variation in distance to the snowmobile, inexact timing of each RES
survey (~~the due to slightly varying~~ sounding ~~plus~~and processing time ~~of the stacked measurements is slightly varying but~~
~~typically ~1 s~~) and the towed sledges not always accurately following the path of the snowmobile. The vertical accuracy is
<0.5 m.

185

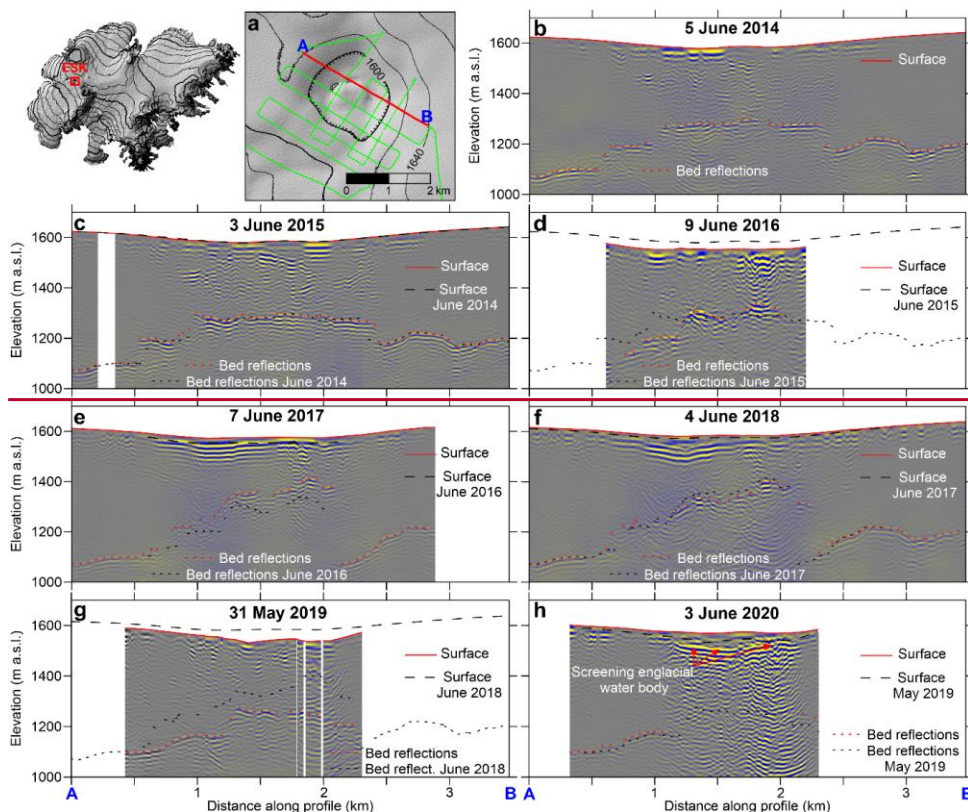

Figure 2 a: The initial obtained RES survey route of ESC (location on corner inlet) in 2014. The DEM presented with shaded relief and contour map (20 m interval) was obtained from TanDEM-X data acquired 23 September 2015. **b-h:** An example of 2D migrated RES profiles for part of this route (from A to B on a) for all survey years. The vertical exaggeration is 2 fold. On each profile, the traced bed reflection (both from ice bedrock and ice/water interface) and surface elevation are shown along with same information from the survey in the preceding year.

The strong direct wave is estimated as the average wave form measured with the RES over several km long segments and subtracted from the corresponding segment of raw RES measurement. The remaining backscatter, mostly from englacial and subglacial reflectors, is amplified as a function of travel time in order to have the backscatter strength as independent as possible of the depth to the reflectors. This recordings along with the 3D location, M , for each measurement recording and corresponding transmitter and receiver 3D positions ($\frac{\text{half antenna separation}}{2}$, behind and in front of M , respectively, along

Formatted: Font: Bold

the DGNS profile) were used as ~~inputs~~input into 2D Kirchhoff migration (e.g. Schneider, 1978), programmed in Matlab (Mathworks). The migration was carried out assuming a radar signal propagation velocity of the radar signal through the glacier, $c_{gl} = 1.68 \times 10^8 \text{ m s}^{-1}$ (corresponding to c_{gl} for dry ice with density of 920 kg m^{-3} (e.g. Robin et al., 1969); the choice of c_{gl} and validation from borehole survey is discussed in section 4.1.3) and a 500 m width of the radar beam width illuminating the glacier bed. This results in profile images as shown in Fig. 2. The x- and y-axis of these images correspond to driven the profile length and elevation in with a horizontal resolution of 5 m, and the y-axis corresponds to m a.s.l., respectively. The image pixel dimension is $dx = 5 \text{ m}$ and $dy =$ with a vertical resolution of 1 m, corresponding. This corresponds roughly to the horizontal sampling density when measuring with a $\sim 1 \text{ s}$ interval at $\sim 20 \text{ km hour}^{-1}$, and the $\sim 80 \text{ MHz}$ vertical sampling rate (in 2014–2017; it is 120 MHz for a new an upgraded receiver unit used in 2018–2020).

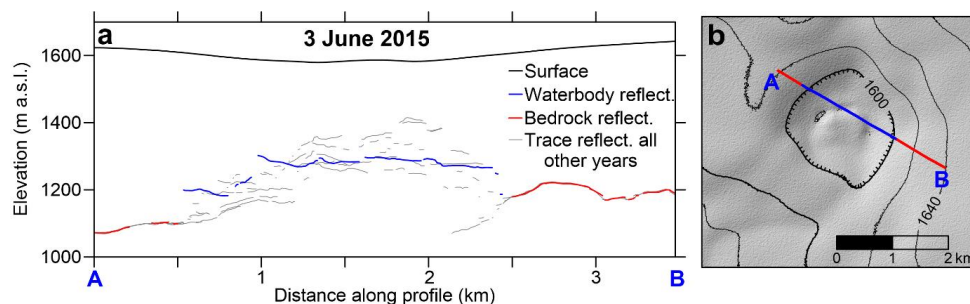

Figure 3 a: The traced reflections in 2015 (blue and red) for the same section of the RES survey route as in Fig. 2 compared with traced reflections of all other years (grey) from this profile section. This is used to classify traced reflections in 2015 as reflections from the roof of a water body (blue) and bedrock (red). The vertical exaggeration is 2-fold. **b:** The corresponding classification for 2015 posted on a TanDEM-X DEM in September 2015.

Backscatter from the glacier bed, which at this stage can both be ice-bedrock and ice-water interfaces, is usually recognised as the strongest continuous reflections in the 2D migrated amplitude images. The next steps including reflection tracing, sub-sampling of traced reflections from 5 m interval to 20 m interval with filtering and masking of traced reflections near sharp turns in profiles are the same as in Magnússon et al. (in reviewpress).

2.2 Outlining the lake margin

At this stage, both the repeated migrated RES profiles as well as traced reflections were projected to common a length axis common with the axis of the 2014 survey in 2014 (the 2018 survey for the new profiles measured since 2018) to allow direct comparison. Slight difference in integrated length along profiles, due to slight difference profile location between years, can otherwise obscure comparison between profiles. The projection onto a common length axis was only done for segments where the repeated profiles are $< 50 \text{ m}$ from the original profile. At locations where this deviation was 15–50 m it was considered whether differences in traced reflections were related to a mismatch between profile locations. The traced reflections were first

compared in areas at or outside the rim of ESC, undoubtedly ~~also outside the subglacial lake margin~~ showing fixed bedrock surface for all surveys. The median elevation difference for the traced reflection in these areas, when compared to the master (2014), was used to bias-correct individual surveys in 2015–2020 towards the master, always resulting in <2.5 m vertical shift (in 2018 and later, the shift is obtained from comparison with an interpolated bedrock DEM based on surveys from previous years). At this stage, the comparison of the profiles (Fig. 2–3) reveals areas for which the elevation of the traced reflections (median corrected in 2015–2020) is unchanged at the temporal minimum, between 2 or more survey dates, indicating reflections from bedrock for corresponding surveys. The comparison also reveals areas where the traced reflection of a given survey is clearly above the traced reflection of another, designating a reflection from an elevated ice–water interface. This helps identifying the parts of a profile that are reflections from the lake roof (Fig. 3–3), which for the ESC is not at all revealed by a flat reflection. It also reveals that the edge of the lake is commonly characterised by relatively steep side walls, which further helps pinpointing the lake edge where repeated reflections from the bedrock were not obtained, as in 2016 and 2019 when the lake area was at its smallest. The lake margin was then approximated in between the RES profiles to obtain the lake outlines and area (Fig. 4). Some of the RES profiles in 2014 and 2015 did not fully span the areal extent of the lake. The lowering during the 2015 jökulhlaup (see section 2.4) was therefore used to further guide this approximation of the 2015 lake margin where RES observations on the lake edge are not available. The obtained 2015 coverage and observed advance of the margin in 2014–2015 from the RES profiles was used to approximate considered when approximating the 2014 lake margin, where this limitation applies to the 2014 survey. The drawing outlines of the lake margin in 2016–2020 was, however, done based on, obtained from the RES data alone. The by manually drawing lines between obtained lake margin positions in profiles. For some years, a part of the lake margin is rather subjectively drawn. This is particularly the case for the south part of the lake margin in 2017–is, which should only be considered as a rough estimate (dotted line in Fig. 4d) since this part of the lake margin was beneath the snow covered supraglacial lake (Fig. 5), which corrupted/obstructed the RES data/signal obtained in this part of the cauldron. In 2018, the supraglacial lake was smaller and the margin of the subglacial lake had advanced beyond the extent of the supraglacial lake, hence the margin/supraglacial lake did not obscure the detection of the 2018 subglacial lake is expected to be quite accurate. Subglacial lake margin. Similar defects in the 2020 RES data (Fig. 2h2i), likely caused by englacial water bodies, made it impossible/impossible to detect part of the southern lake margin, and may result in a somewhat uncertain lake area. The approximated margin in 2020 (dotted line in Fig. 4g) is, however, constrained by traced reflections from bedrock a short distance south of the drawn margin, hence the estimated lake area in 2020 is near its expected upper limit. lake area in 2020 can't be much larger than the estimate presented here. Based on the above, we expect the uncertainty of the lake area to be ~0.1 km² for all years except in 2017 and 2020 when we estimate the uncertainty as ~0.3 km² and ~0.2 km², respectively.

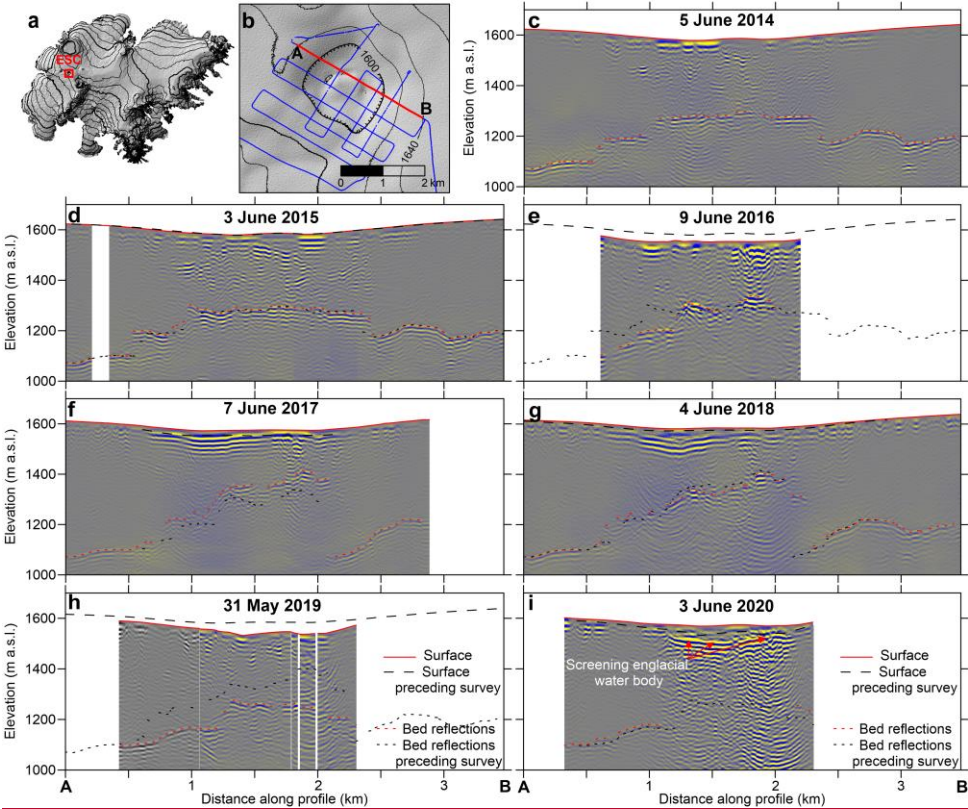

2.3 Creation of bedrock DEM and lake thickness maps

The records of traced reflections were ~~now~~ split in two groups, using the lake outlines derived above: i) reflections from bedrock, and ii) reflections from the roof of the subglacial lake. The former data group, including was merged into a single

260

data set. This includes data from profiles obtained in the vicinity of ESC outside the area of repeated RES survey (mostly in 2017 and 2019), were now merged into a single data set., see Fig. 4 d and f). The record of traced bedrock reflections covers fairly well display good coverage across the bedrock beneath the cauldrons except where the lake is present for all surveys (Fig. 4). In addition to the RES, the bedrock elevation beneath the cauldrons has been measured directly through two boreholes (Gaidos et al., 2020), which fortunately were located within the RES data gap. From the bedrock record, including borehole measurements, a bedrock DEM (Fig. 6a) with 20m x 20m cell size has been interpolatedconstructed using the kriging interpolation method (processed using a function in Surfer 13 © Golden Software; LLC).

This is used to classify traced reflections in 2015 as reflections from the roof of a water body (blue) and bedrock (red). The vertical exaggeration is 2-fold. **b:** The corresponding classification for 2015 posted on a TanDEM-X DEM in September 2015.

The filtered and revised records of traced reflections from a given year obtained within the corresponding lake margin were assumed to originate from the lake roof at that time. An independent survey of the lake roof elevation was carried out through a borehole close to one of the RES profile only 4 days after RES survey in June 2015 (Fig. 7), which supports our choice of e_{gr} (see section 4.1.3).

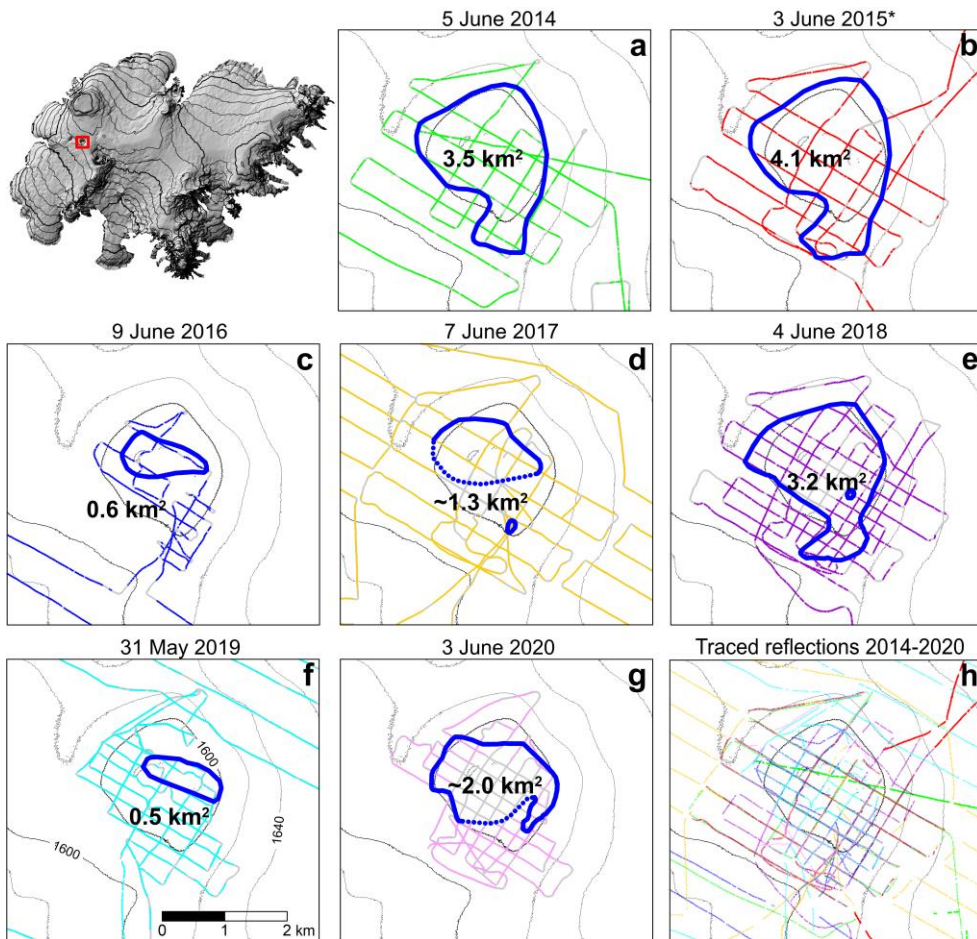

Figure 4 a–g: Traced bed reflections (both ice-water and ice-bedrock reflections) for the RES surveys in 2014–2020. Locations of traced reflections of each survey are displayed in different colours on top of the survey route of each year (shown as grey lines). The contour map shows the surface elevation in September 2015 (TanDEM-X). Polygons (blue line) and numbers indicate derived margin and area of the subglacial lake for corresponding year. Poorly constrained sections of the lake margin are shown with a dotted line. Locations of all traced reflections with corresponding colour coding are shown in **h**. * One profile in 2015, surveyed by driving from the cauldrons centre out of study area towards northeast, was acquired in February 2015. It was only used to approximate the position of the lake margin in spring 2014 and 2015 and for tracing bedrock reflection outside the lake.

The lake roof records of individual survey epochs were ~~now compared with~~ then differenced from the interpolated bedrock DEM to obtain lake thickness for each data point. ~~Coordinate lists (20 m between points) of the determined lake. The lake outlines for each epoch with~~ were converted to input data points (with 20 m interval) with prescribed lake thickness ~~set to of~~ zero ~~were added to the corresponding RES lake thickness record~~ before interpolating each lake thickness map (using the Kriging function in Surfer 13) for each year (Fig. 6). At a few locations, minor adjustments of the interpolated maps were made because of disagreement between crossing profiles. This only occurred in areas of very steep topography in the lake roof where 2D migration tends to fail, particularly for profiles driven perpendicular to the slope direction of the underlying lake roof (see section 4.1.2). In such cases, the manual adjustment favoured data from profiles which were more parallel to the roof's slope direction. Lake volumes (Fig. 6) were obtained by integrating the individual thickness maps. In 2020, only the area could be obtained from the RES data; the lake topography was only partly surveyed (Fig. 6h) due to strong internal reflections (see section 2.1), prohibiting direct integration of the lake volume. In this case, the volume of the lake was estimated assuming a linear relation between the lake area and volume using the values obtained in 2014–2019 (Fig. 6i).

2.4 Elevation changes and released volume of water during jökulhlaups in 2015 and 2018

The DEMs used to measure the surface lowering of the ESC during the jökulhlaup in 2015 were deduced from Interferometric Synthetic Aperture Radar (InSAR) data acquired by ~~during~~ the TanDEM-X ~~twin-satellite~~ satellite mission on 23 September and 10 October, a few days before and approximately a week after the jökulhlaup. The DEMs are processed by extracting the topographic information from the InSAR data in the same manner as described by Rossi et al. (2012). ~~The DEM difference~~ Differencing the two DEMs reveals the area affected by the depletion of the subglacial lake as a clear anomaly, outlined in Fig. 8a7a, as well as ~~the~~ surface lowering above the flood route from the lake south of the cauldron. The DEM difference was corrected for ~~actual~~ near homogenous surface elevation changes between the two dates, unrelated to the jökulhlaup, and for slowly varying elevation errors in the DEMs, e.g. caused by different penetration of the radar signal into the glacier surface at the two dates (Rossi et al., 2016) ~~a correction was deployed.~~ Around the outlined anomaly, excluding the flood route, a ~500 m wide reference area was defined, where the elevation changes due to the 2015 jökulhlaup are expected to be insignificant (within few decimetres). The method of least squares was used to fit a linear plane through the obtained elevation difference within this reference area. ~~This linear plane was, which we then~~ subtracted from the elevation difference between the two DEMs.

The DEM prior to the jökulhlaup in early August 2018 was constructed from a DEM obtained as part of the ArcticDEM project (Porter et al., 2018) in August 2017, corrected with the DGNSS profiles acquired on 4 June, during the 2018 RES survey of ESC (Fig. 4e). The elevation changes, during the jökulhlaup, were obtained by comparing this DEM with the airborne radar altimetry profiles with approximate accuracy of 1–2 m (for more details see Gudmundsson et al., 2016), acquired on 9 August, a few days after the jökulhlaup (Fig. 8d7d). The difference between the DEM and the radar ~~altimetry profiles~~ were ~~was~~

interpolated with kriging to obtain a map of elevation changes during the jökulhlaup. To compensate for ~~actual~~-surface elevation changes from 4 June and 9 August, unrelated to the ~~jökulhlaup~~jökulhlaup, a linear plane was again subtracted from the obtained map of elevation changes. The linear plane was obtained in the same way as for the jökulhlaup in 2015, except the westernmost part of the reference area from 2015 was excluded, due to elevation changes related to a jökulhlaup from WSC, which occurred at the same time as the flood from ESC in 2018.

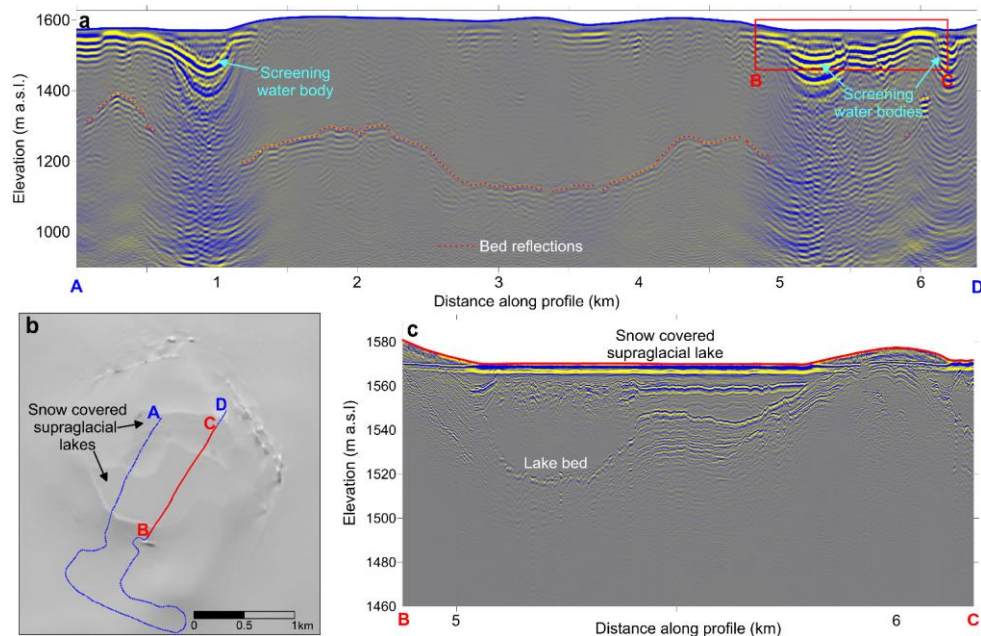

Figure 5 a: The low frequency (5 MHz) RES survey (2D migrated) on 7 June 2017 from location A to D (location shown in b) revealing features which induce ringing in the received radar reflections, completely screening reflections from the glacier bed (traced reflections indicated with a red dotted line). The flat glacier surface above these features along with Landsat-8 optical image in August 2017 (b) clearly reveals these features as snow covered supraglacial lakes. RES survey on 8 June 2017 with 50 MHz Mini-radar (c) along subsection B to C (location shown in b) repeating the low frequency survey (corresponding part of the low frequency RES profile is indicated with red box in a) further confirms this. Note that the elevation projection for c is carried out using $c_p = 1.68 \times 10^8 \text{ m s}^{-1}$. The propagation velocity through the media above the supraglacial lake bed is much lower, hence the depth of the lake as indicated in c is overestimated. The vertical exaggeration is 2.5:1 and 5:1 in a and c, respectively.

To obtain a measurement of water volume released during the jökulhlaups, the elevation changes were integrated within the outlined area of lowering due to the depletion of the lake. The area where this lowering was more than few decimetres is quite distinctive in the 2015 elevation change map. The less accurate elevation change map during the 2018 jökulhlaup, due to the sparse altimetry data after the jökulhlaup (profile location shown in Fig. 8d7d) and a larger time gap between the pre-jökulhlaup

DEM and the jökulhlaup (~2 months compared to only few days in 2015), made it difficult to directly outline the area of lowering in 2018. It was therefore assumed that the lowering area was the same as in 2015 (dashed line in Fig. 8e7c). The integrated volume change within this area was 280 ± 5 GI (10^6 m^3) for the jökulhlaup in 2015 and 180 ± 18 GI in 2018. ~~The uncertainty corresponds to a possible bias of 0.25 m and 1.0 m for the elevation change maps for in 2015 and 2018, respectively, for the area of integration). To estimate the, It is approximated from the variations in obtained elevation difference outside the area of integration. The volume losschange during the jökulhlaup, corresponding to the water released from the lake, we also need to considerconsists of both the volume integrated from the surface elevation change detectable from the DEMs and the formation of crevasses formed during the jökulhlaups, which can penetrate deep into the glacier and are not represented in the post-jökulhlaup elevation data. The crevasse field surrounding ESC after the jökulhlaup in 2015 formed an ~8 km long arc. Assuming that the cumulative width of the crevasses across the 300–400 m wide crevasse field is 100 m at the surface; and that this width decreases linearly with depth to 0 m at 100 m depth, results in a volume of 40 GI (Guðmundsson et al., 2018). In 2018, the crevasse field had a similar area (shorter arc but wider) resulting in the same crevasse volume estimate. The uncertainties of these estimates are assumed to be rather high or 50% of the derived values. By addingCombined with the estimated crevasse volume, the estimated volumeuncertainty of water releasedvolumes from the subglacial lake increases to 320+DEM difference results in 20 GI during the jökulhlaup in 2015 and 220+and 30 GI uncertainty in the lake release volume in the 2015 and 2018 jökulhlaup.—jökulhlaups, respectively.~~

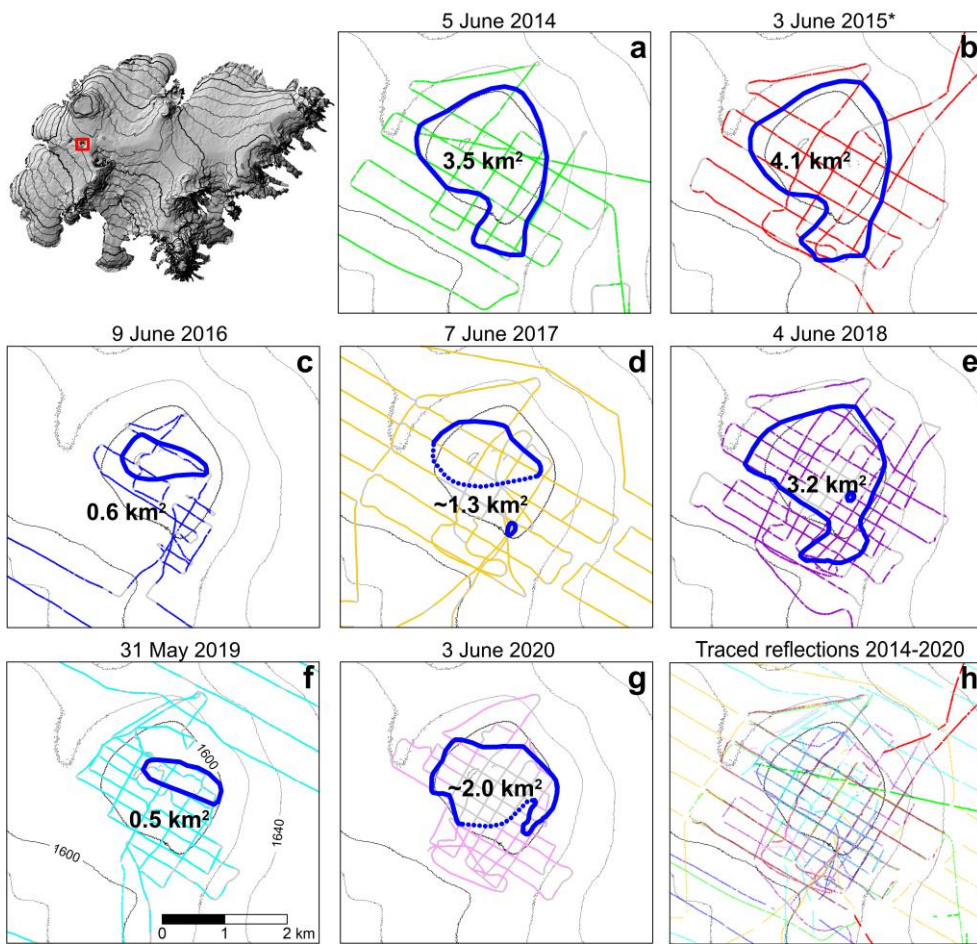

Figure 4 a–g: Traced bed reflections (both ice-water and ice-bedrock reflections) for the RES surveys in 2014–2020. Locations of traced reflections of each survey are displayed in different colours on top of the survey route of each year (shown as grey lines). The contour map shows the surface elevation in September 2015 (TanDEM-X). Polygons (blue line) and numbers indicate derived margin and area of the subglacial lake for corresponding year. Poorly constrained sections of the lake margin are shown with a dotted line. Locations of all traced reflections with corresponding colour-coding are shown in **h**. * One profile in 2015, surveyed by driving from the cauldron's centre out of the study area towards northeast, was acquired in February 2015. It was only used to approximate the position of the lake margin in spring 2014 and 2015 and for tracing the bedrock reflection outside the lake.

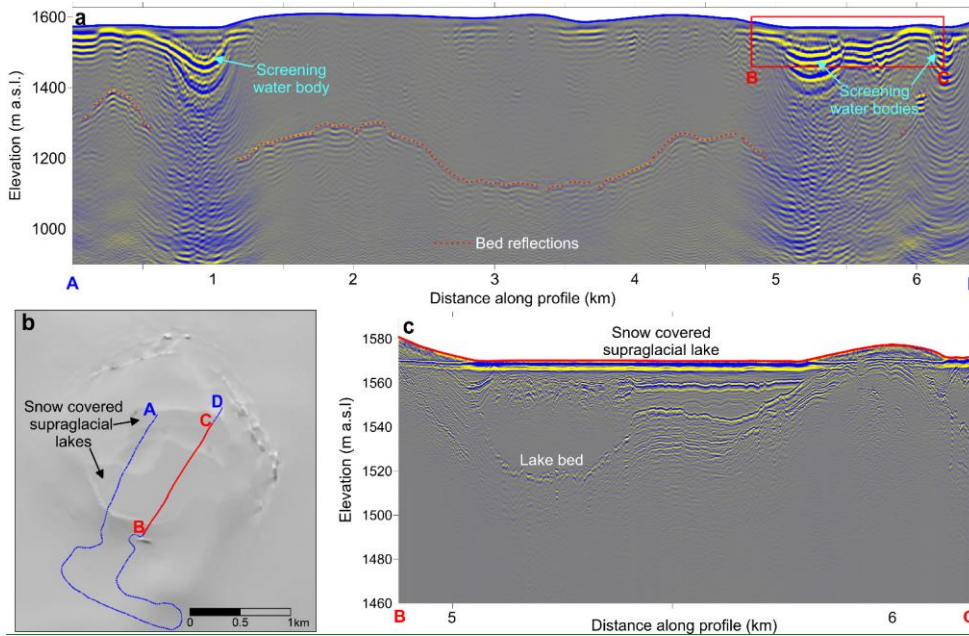

Figure 5 a: The low frequency (5 MHz) RES survey (2D migrated) on 7 June 2017 from location A to D (location shown in **b**) revealing features which induce ringing in the received radar reflections, completely screening reflections from the glacier bed (traced reflections indicated with a red dotted line). The flat glacier surface above these features along with the Landsat-8 optical image in August 2017 (**b**) clearly reveals these features as snow covered supraglacial lakes. RES survey on 8 June 2017 with 50 MHz Malå radar (**c**) along subsection B to C (location shown in **b**) repeating the low frequency survey (corresponding part of the low frequency RES-profile is indicated with red box in **a**) further confirms this. Note that the elevation projection for **c** is carried out using $c_M=1.68 \times 10^8 \text{ m s}^{-1}$. The propagation velocity through the media above the supraglacial lakebed is much lower, hence the depth of the lake as indicated in **c** is overestimated. The vertical exaggeration is 2.5:1 and 5:1 in **a** and **c**, respectively.

2.5 Validation of the RES results

We did not attempt to estimate the uncertainty of the lake volumes derived from the RES data directly. Various factors, which are hard to quantify can contribute to this uncertainty and the dependency between different uncertainty factors is unclear and therefore difficult to combine into a single uncertainty value (discussed further in section 4.1). Instead, the lake volumes derived from the RES data were validated by comparing them with the volume of water released during jökulhlaups, obtained from measured surface lowering (Fig. 7–8). The results of the validation are described in section 3.1.

3 Results

3.1 Lake area and volume

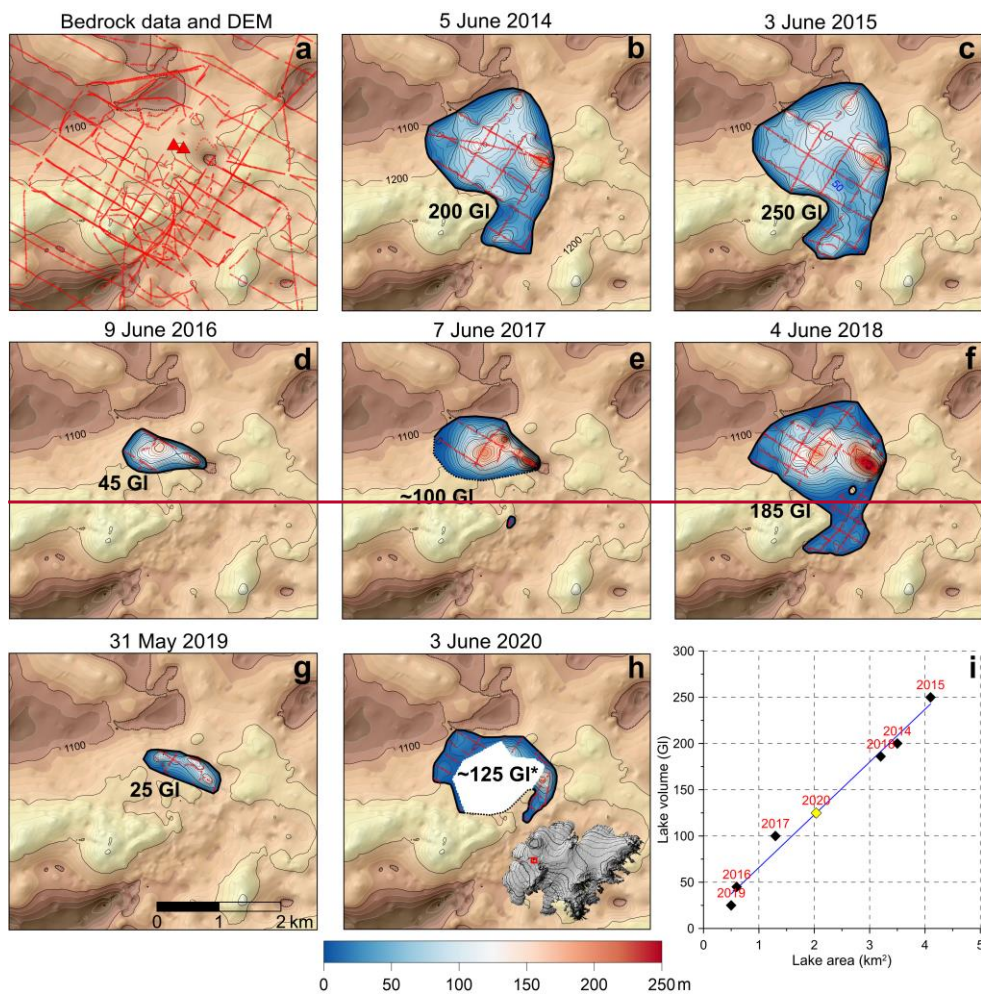

The evolution of the lake area inferred from the RES surveys in 2014–2020 is shown in Fig. 4. The minimum area
~~Results~~

~~The evolution of the lake area inferred from the RES surveys in 2014–2020 is shown in Fig. 4. The minimum areas~~ of 0.5–0.6 km², was observed less than a year after the 2015 and 2018 jökulhlaups, while the maximum of 4.1 km² was observed in June 2015, ~4 months prior to a jökulhlaup. At the time of this observed maximum lake area in 2015, almost 5 years had passed from the previous jökulhlaup from ESC in July 2010 (Guðmundsson et al., 2018). ~~The~~In comparison, the lake had ~~reached an~~
385 ~~area of~~expanded to 3.2 km² in June 2018, two months prior to ~~at~~the 2018 jökulhlaup.

The lake development in terms of volume and shape is shown in Fig. 6. ~~It indicates rather~~The strong positive linear relation between the area and volume of the subglacial lake ~~(is demonstrated in Fig. 6i).~~. The variation of lake volume obtained with RES along with the estimated volumes of water released during the jökulhlaups extracted from surface elevation changes (Fig. ~~8e7c~~–d) are displayed in Fig. ~~98~~. The RES surveys indicate lake ~~volume~~volumes <50 GI in 2016 and 2019, less than a year
390 after jökulhlaups, which strongly suggests that the lake drained completely or was reduced to an insignificant volume in the preceding jökulhlaups. The lake volume prior to jökulhlaup and at the released volumes during them should therefore be comparable justifying further the validation of the RES results (section 2.5). A maximum volume of 250 GI is derived for June 2015 compared with a volume of 320±20 GI released during the jökulhlaup ~4 months later. The survey in June 2018 yields a volume of 185 GI, while the released volume in August the same year was 220±30 GI. ~~The~~At the onset of the 2018 jökulhlaup
395 ~~was — observed — from — real-time — monitoring — with — a — GNSS — station — operated — in — ESC (https://brunnur.vedur.is/gps/eskaftarketill.html) by IMO, few days prior to the peak discharge in the Skaftá river (Fig. 1). At the time of observed onset,~~ the water volume in the lake had already been estimated to be 180 GI, using the available RES record from ESC in 2014–2018 (Guðmundsson, et al., 2018), indicating the applicability. Some of our RES survey approach to evaluate the expected hazard the difference between the volumes obtained from RES in June 2015 and 2018 and from a
400 jökulhlaup:

surface lowering during jökulhlaups 2–4 months later is likely explained by more rapid lake growth during summers compared to winter due to inflow of melt water from the glacier surface. With this in mind, the errors in RES volumes were probably <20% and <10% in 2015 and 2018, respectively. The development of the lake volume in 2010–2020 assuming it drained completely in the jökulhlaupjökulhlaup in July 2010, mimics a saw tooth curve (Fig. ~~98~~ a) with an approximately fixed filling rate of ~60 GI a⁻¹ between jökulhlaups (Fig. ~~9–b8b~~). The values in 2014 and 2015 are slightly offset from this trend, possiblepossibly due to a less dense profile network then than for later surveys. This may explain the better match in 2018 between the lake volume derived from the RES survey and the released volume few months later, compared with 2015. If the RES surveys of 2014 and 2015 are excluded, the filling rate between jökulhlaups is ~65 GI a⁻¹. It is worth noting how poorly
405

410 ~~the measured surface elevation at ESC centre correlates with the lake volume beneath~~ Given how well the combined record of lake volumes from RES and observed surface lowering fit a linear relation with time elapsed since the previous jökulhlaup (Fig. 8b) we expect the uncertainties in the RES volumes to be 10–20%, as in 2015 and 2018, except when the lake is small (<100 Gl) and therefore not posing significant hazard (uncertainties <10 Gl should not be expected with this approach). By measuring a denser RES profile network as done since 2018, the uncertainty has probably lowered to ~10% for favourable surveying conditions.

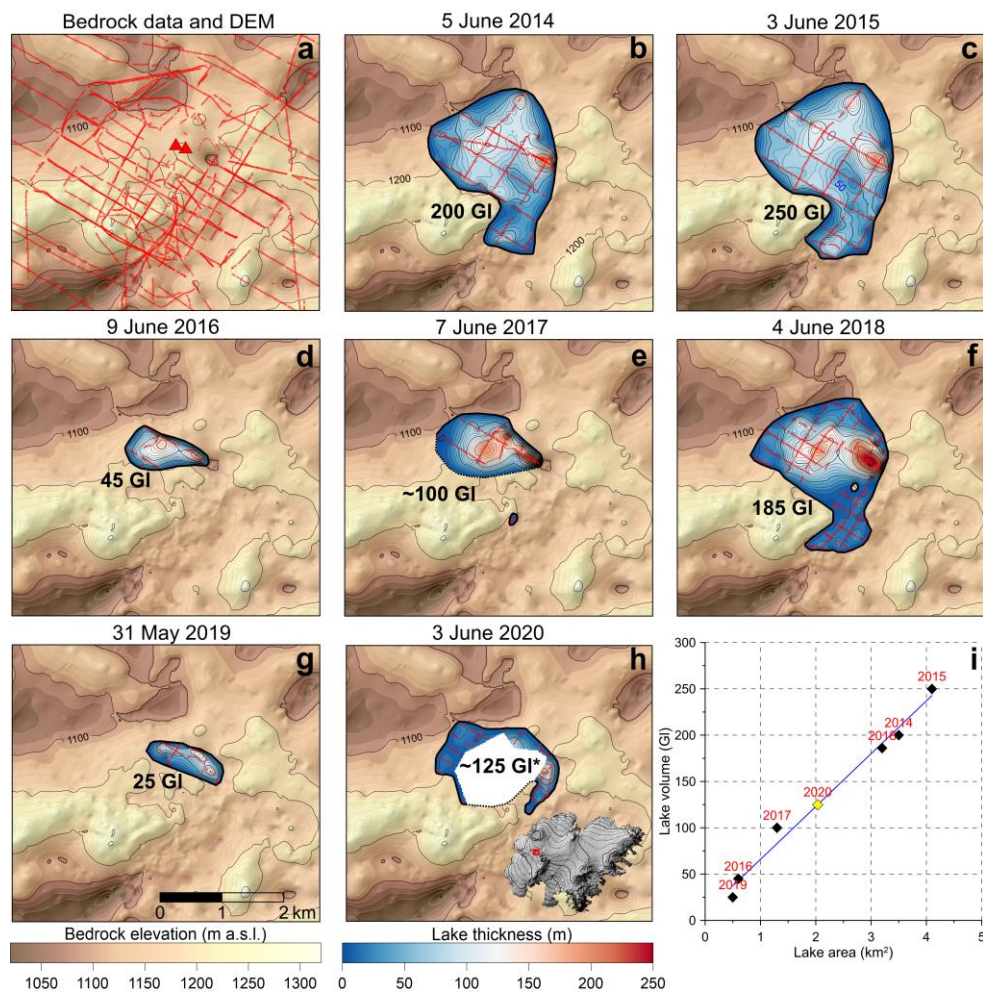

Figure 6 a: The location of traced reflections classified as reflections from bedrock (red lines) in the combined 2014–2020 RES record along with elevation of bedrock measured through boreholes (red triangles) used to interpolate a DEM of the bedrock beneath **ESKESC** and near vicinity. This DEM, represented with the elevation contour map (20 m contour interval), is shown in the background of **a–h**. **b–h:** Maps of lake thickness (colour bar below) along with the location of traced reflections classified as reflections from the lake roof (red lines), used to interpolate lake thickness map for each survey. Lake volumes integrated from the lake thickness maps are displayed in GI (10^6 m^3). **i:** The

lake volume posted as function of lake area (in 2014–2019; black diamonds), which constrains a linear relation (blue line) used to estimate the lake volume in 2020 (value marked with * in h and yellow diamond in i).

Figure 7

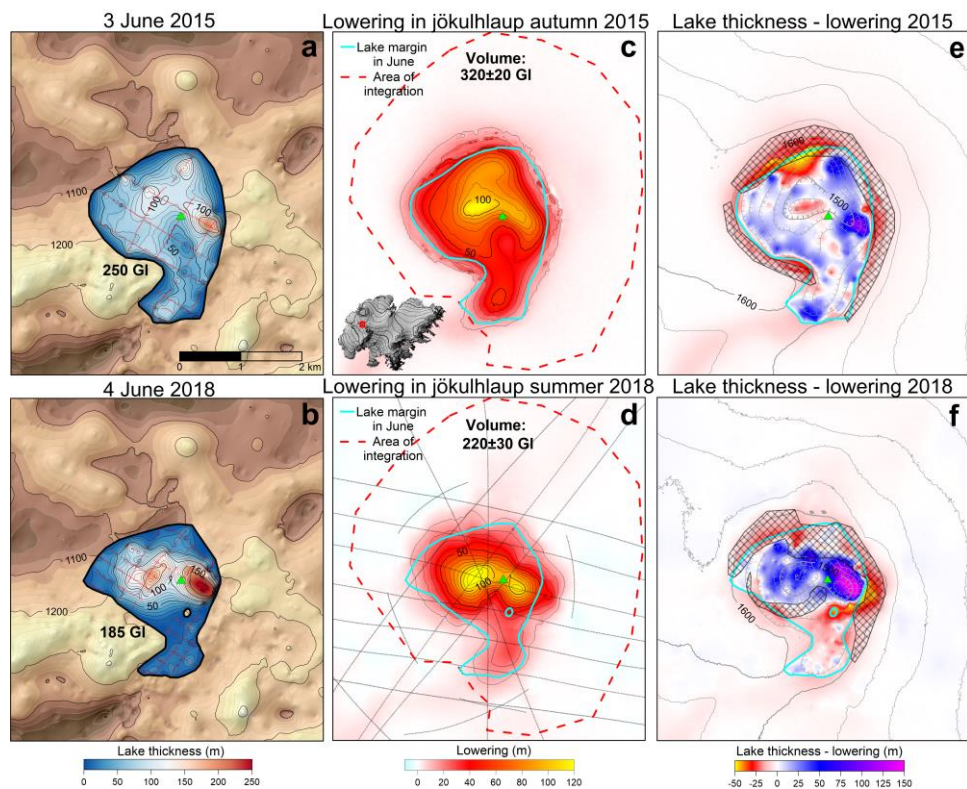

Figure 7 a–b: The lake thickness maps for ESC. **a–b:** Cross-section over the centre part of ESC from location A to B (shown in **c**) revealing bedrock, lake and ice thickness, 4 and 2 months before the jökulhlaups in 2015 (**a**) and 2018 (**b**), respectively. The lowering along this cross-section during the subsequent jökulhlaup (derived from Fig. 8) is shown in the upper part of each panel. Note that the y-axis is without vertical exaggeration. **d:** Comparison of lake roof elevation measured with RES, 3 June 2015 (blue numbers and diamonds), and through borehole, 7 June 2015 (red number and x). The borehole location relative to the cross-section A to B is shown in **a** and **c**. Red box in **e** indicates the area shown in **d**.

ESC (Fig. 9). This indicates the governing role of ice dynamics for filling up the cauldron surface depression, while the contribution of water accumulation in the lake to surface elevation changes is small in comparison; large proportion of the accumulated water simply replaces ice melted beneath ESC.

A striking feature in the lake shape for all observations are steep side walls, clearly represented in Fig. 7a–b, typically exceeding 45° slopes and sometimes even 60°. Despite the apparent linear relation between the lake volume and area (Fig. 6i) the overall shape of the lake varies substantially during the study period. In 2014 and 2015, before the jökulhlaup in autumn 2015, the

Formatted: Heading 2

440 water was distributed much more evenly over the lake area than in 2018, when both the lake volume and area were close to the values obtained for 2014. In 2018, the lake water was, however, more concentrated close to the ESC centre with the maximum lake thickness above the crater-shaped bed depression beneath the eastern side of ESC (Fig. 6–8), ~0.5 km east of boreholes (Fig. 6a and 7a). The lake margin also appeared to be different in 2018. The steep side walls surrounded the bulk of the lake but between these walls and the outlined lake margin was an area with typical lake thickness of 10–30 m (see Fig. 6f and left side of Fig. 7b). This clear difference in the lake shape before the 2015 and 2018 jökulhlaups is also apparent in the
445 lowering during these jökulhlaups (Fig. 8c–d). Despite greater lake thickness beneath the ESC centre in 2018 the surface elevation was similar as in 2015 (Fig. 7a–b and Fig. 9a). The ice prior to the 2018 jökulhlaup above the lake was however relatively thin; in 2017 the minimum ice thickness was only ~150 m but it had increased to ~180 m in 2018. Prior to the 2015 jökulhlaup when the lake water was more evenly distributed the corresponding values were ~260 m and ~280 m in 2014 and 2015, respectively. The outward migration of the lake margin in 2014–2015 was characterised by outward propagation of the
450 steep side ice walls defining the lake margin by typically 50–150 m. The steep side walls also seem to characterize the lake margin in 2017 but this was quite different in 2018. The steep side walls still surrounded the bulk of the lake and these walls had advanced from 2017 but the lake margin had advanced much further, typically 100–1000 m (Fig. 6e–f), due to the formation of previously mentioned 10–30 m thick water layer surrounding the steep lake walls.

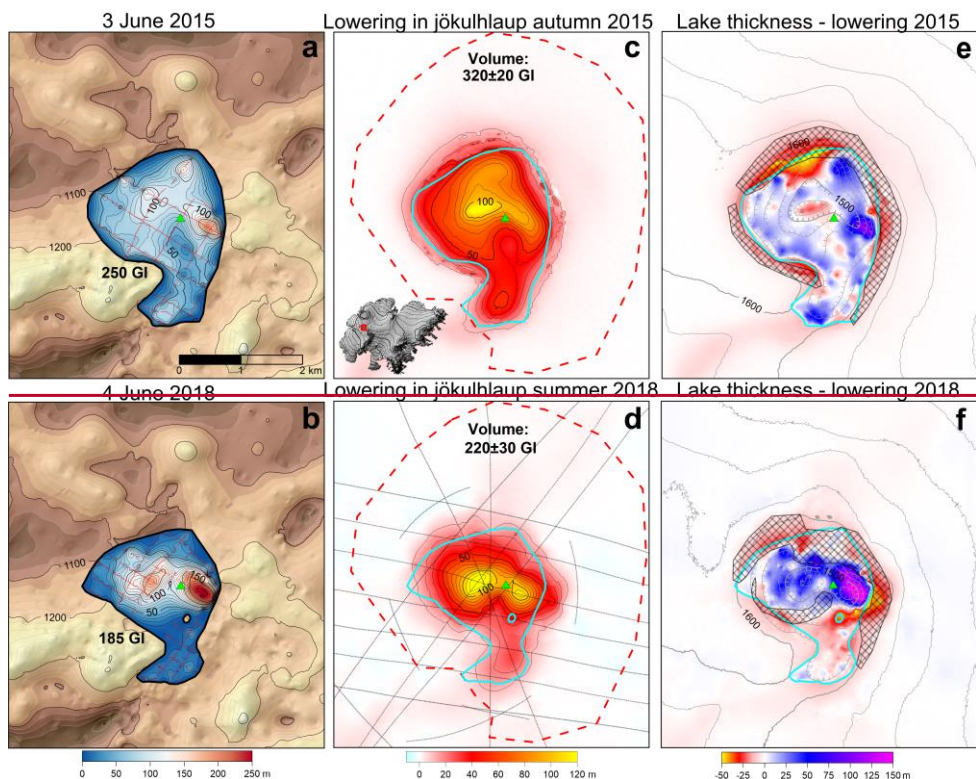

Figure 8 a–b: The lake thickness maps for ESC (colour bar below) 4 and 2 months before the jökulhlaups in 2015 and 2018, respectively (from Fig. 6c and 6f). **c–d:** Maps of glacier surface lowering (colour bar below) during these jökulhlaups with lake margin (cyan line) from **a** and **b**. The dashed red line indicates the area of integrated surface lowering corresponding to the area of notable surface lowering during the 2015 jökulhlaup. The grey lines in **d** indicate the locations of radar altimetry profiles surveyed from an airplane on 9 August 2018, a week after the jökulhlaup. The total volume of the lake integrated from the lake thickness maps (**a–b**) and the released volume integrated from the surface lowering during jökulhlaup adding estimated volume of crevasses (**c–d**) are displayed in GI (10^6 m^3). **e–f:** The difference between lake thickness obtained by RES, in 2015 and 2018, and the lowering during the following jökulhlaup. Polygons filled with diagonal crosses indicate the areas of large crevasses formed during the jökulhlaups as outlined from Fig. 4b–e1c–d. The contour maps indicate surface elevation (20 m contour interval) from TanDEM-X, 10 October, 2015 (**e**) and from the altimetry profiles on 9 August 2018 (**f**) as explained in section 2.4. Green triangle in **a–f** indicate location of a GNSS station operating during both jökulhlaups.

Figure 9 It is worth noting how poorly the measured surface elevation at the ESC centre correlates with the lake volume beneath the cauldron (Fig. 8). This indicates the governing role of ice dynamics for filling up the cauldron surface depression, while the contribution of water accumulation in the lake to surface elevation changes is small in comparison; large proportion of the accumulated water simply replaces ice melted beneath the cauldron.

3.2 Lake shape

A striking feature in the lake shape for all observations are steep side walls, clearly represented in Fig. 9a–b, typically exceeding 45° slopes and sometimes even 60°. Despite the apparent linear relation between the lake volume and area (Fig. 6i) the overall shape of the lake varies substantially during the study period. In 2014 and 2015, before the jökulhlaup in autumn 2015, the water was distributed much more evenly over the lake area than in 2018. Even though the lake volume and area in 2018 were close to the values obtained for 2014, the lake water was more concentrated close to the ESC centre with the maximum lake thickness above the crater-shaped bed depression beneath the eastern side of ESC (Fig. 6–8), ~0.5 km east of the boreholes (Fig. 6a and 7a). The shape of the subglacial lake margin also differed between 2015 and 2018. The steep side walls still surrounded the main bulk of the lake in 2018. However, the lake generally extended few hundred meters outside these walls with an area of 10–30 m thick water (see Fig. 6f and left side of Fig. 9b). This clear difference in the lake shape before the 2015 and 2018 jökulhlaups is also apparent in the lowering during these jökulhlaups (Fig. 7c–d). Despite greater lake thickness beneath the ESC centre in 2018 (Fig. 9a–b and Fig. 7a–b) the surface elevation was similar as in 2015 (Fig. 9a–b and Fig. 8a). Prior to the 2018 jökulhlaup, the ice above the lake was, however, relatively thin; in 2017 the minimum ice thickness was only ~150 m but it had increased to ~180 m in 2018. Prior to the 2015 jökulhlaup, when the lake water was more evenly distributed, the corresponding values were ~260 m and ~280 m in 2014 and 2015, respectively. The outward migration of the lake margin, typically by 50–150 m, appear as outward propagation of the steep ice walls that defined the lake margin. The steep side walls also seem to characterize the lake margin in 2017 but this was quite different in 2018. Due to the formation of previously

Formatted: Heading 2

mentioned 10–30 m thick water layer surrounding the steep lake walls in 2018, the lake margin typically advanced by 100–1000 m (Fig. 6e–f).

3.3 Lake topography vs. lowering during jökulhlaups in 2015 and 2018

~~a: The development of the lake volume (left y-axis) beneath ESC in 2010 to 2020 obtained from the RES data (black and yellow diamonds) and derived surface lowering during jökulhlaups adding estimated volume of crevasses (cyan diamonds). The latter includes estimated uncertainty. It is assumed that the lake drained completely during the jökulhlaups in 2010, 2015 and 2018. Red dots show measured elevation (right y-axis) of ESC centre from radar altimetry and GNSS surface profiling (<http://jardvis.hi.is/skaftarkattlar-yfirbord-og-vatnsstada>). b: The same lake development and cauldrons centre elevation as function of time elapsed since previous jökulhlaup. The solid red line shows a linear fit through origin (zero volume at time zero) for the lake development; the dashed red line excludes the RES surveys in 2014–2015.~~

When comparing the obtained lake thickness map prior to jökulhlaups and the subsequent lowering (Fig. 7–8 and 9), the surveyed shape of the lake and the lowering shows strong similarities. The lowering appears like a spatially filtered version of the lake thickness shape, with the maxima at approximately the same location and substantial lowering (>5 m) extending typically 200–500 m outside the lake margin as obtained from the RES survey (Fig. 87). Figure 8e7e–f shows the derived difference between the lake thickness in spring 2015 and 2018 and the lowering during the jökulhlaups a few months later, indicating when the lake most likely drained completely or was reduced to an insignificant volume (Fig. 8). This difference, therefore, indicates where the ice became thinner or thicker during and shortly after the jökulhlaups, and the outlines of excessively crevassed areas formed during these floods. The main thinning areas as well as the main crevasse areas are located at or outside the main ice walls of the lake. In 2015, this coincides with the lake margin but not in 2018 as mentioned above. The main exception from this is the derived thinning in the northern part of ESC in 2015, which extends significantly into the cauldron. The lake thickness in this area is, however, not covered with direct RES observation (red profiles in Fig. 8a7a), hence, the apparent thinning may be an artefact, as the relatively sparse RES profiling did not capture the amount of water stored in this area prior to the 2015 jökulhlaup. This further supports that the true lake volumes in 2014 and 2015, based on the RES data, isare underestimated. The thickening areas approximately correspond to the lake roof within the ice wall of the lake and the surrounding crevasse fields formed during the jökulhlaups. The thickening in 2015 was wide spreadwidespread, typically less than 40 m and at the centre of the cauldron our estimation suggests thinning, but that may be due to scarce bedrock data at this location (Fig. 6a). In 2018, the thickening was much more localized and exceeded 40 m for substantial part of the area where the ice grew thicker. In both jökulhlaups, the area above the crater-like bed depression beneath at the eastern side of the cauldron yielded by far the greatest thickening. In 2015, the derived thickening at this location was up to 110 m, while in 2018 it was up to 170 m.

4 Discussions Discussion

4.1 The uncertainty and limitations of the RES survey for quantifying the lake development

In the results presented, we did not attempt to estimate the uncertainty of the lake volumes derived from the RES data specifically. Instead, the results derived from the RES data were validated by comparing them with the volume of water released during jökulhlaups, obtained from measured surface lowering. The good agreement between the RES surveys before the jökulhlaups in 2015 and 2018 and the volumes obtained from surface lowering during these jökulhlaups (Fig. 8–9) and how well the two datasets fit a linear relation with time elapsed since the previous jökulhlaup (Fig. 9b), suggest that the errors of the lake volumes derived from the RES data may typically be 10–20%, except when the lake is small and therefore not posing significant hazard. By measuring a denser RES profile network as done since 2018, the error has probably been lowered to ~10% when the surveying conditions are favourable. This can be considered low given the uncertainty factors that affect the RES surveys. These include uncertain value of c_{gl} , limitations of the 2D migration applied, and interpolation error. There are various uncertain factors, which may contribute to errors in the results derived from the RES data. This includes uncertain value of c_{gl} , limitations of the 2D migration applied, and interpolation errors due to sparse data coverage both for obtaining the bedrock DEM and the lake thickness maps. Each of these factors may produce systematic errors, which can lead to either an under- or overestimated lake volume. It is, however, possible that errors caused by different factors cancel out one another to some degree. Below we further discuss these limitations and conclude with remarks on how these errors relate to the validation (see sections 2.5 and 3.1).

4.1.1 RES data gaps

The bedrock area concealed by the subglacial lake in all RES surveys is 0.35 km² or ~10% of the lake area in 2018 and less than that in 2015. The centre of this gap in the RES bedrock observations is constrained with direct observations of bedrock elevation through boreholes. The contribution of this bedrock data gap to errors in the lake volume estimates is therefore expected to be small, except when the lake is small and mostly within the area of limited bedrock data. At other locations in the RES profile network, reflections from the bedrock have generally been traced at some time point, meaning that for most observations ~~on~~ of roof elevation there is also an observation ~~on~~ of the bedrock elevation at the same location. Interpolation errors outside the bedrock RES data gap, contributing to errors in the lake volume estimate, are therefore mostly related to the interpolation of the lake thickness, not the bedrock elevation.

Supraglacial lakes and englacial water bodies, further discussed below, produce gaps in the data used to interpolate lake thickness maps for some years. For this reason, we consider the uncertainties of the lake volumes obtained in 2017 and 2020 could have errors as high as ~at the upper limit (~20%;%) of the uncertainty range obtained from the validation (section 2.5); in 2017 mostly due to uncertain location of the lake margin, in 2020 due to possible deviations from the obtained linear relation between lake volume and area (Fig. 6i). The survey in 2018 is also affected by similar data gaps. The lake margin is, however,

fairly well constrained and only ~15% (~0.5 km²) of the lake area (3.2 km²) is affected by these data gaps. Interpolation errors in the lake thickness maps are probably resulting in larger lake volume errors in 2014 and 2015 when the distance between RES profiles was 400–500 m, compared with 200–250 m in 2018 and later.

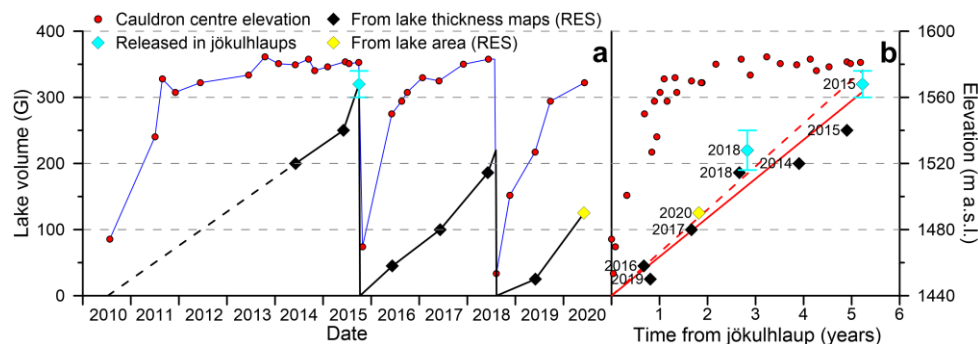

Figure 8 a: The development of the lake volume (left y-axis) beneath ESC in 2010 to 2020 obtained from the RES data (black and yellow diamonds) and derived surface lowering during jökulhlaups adding estimated volume of crevasses (cyan diamonds). The latter includes estimated uncertainty. It is assumed that the lake drained completely during the jökulhlaups in 2010, 2015 and 2018. Red dots show measured elevation (right y-axis) of ESC centre from radar altimetry and GNSS surface profiling (http://iardi.hi.is/skaftarkatlar_vfirbord_og_vatnsstada). **b:** The same lake development and cauldron centre elevation as function of time elapsed since the previous jökulhlaup. The solid red line shows a linear fit through origin (zero volume at time zero) for the lake development; the dashed red line excludes the RES surveys in 2014–2015.

4.1.2 Limitations of the 2D migration

In most glaciological studies applying RES the acquired data applications only allows for 2D migration, which of RES data is possible for locating radar reflections but this requires the assumption that all received radar reflections are only originate from features directly beneath the survey profile. Significant errors in locating reflectors with 2D migration due to this simplification typically arise in areas like the one studied here. This is often not the case beneath glaciers that flow over volcanic regions, where the subglacial topography of the reflecting surfaces is highly variable and particularly complex. This is most pronounced when profiles are surveyed perpendicular to slope direction of the reflective surface but much smaller when the slope and profile directions are in parallel (e.g. Lapazaran et al., 2016). Due to this shortcoming the elevation of the traced reflective bedrock surface tends to be overestimated in the 2D migrated data. If the point in the reflective surface closest to the radar, corresponding to the traced reflection, is not directly beneath the RES profile but cross-track, the obtained ice thickness is underestimated and therefore the elevation of the mapped surface directly below the profile is estimated to be too high. It is never too low unless the traced reflection does not corresponds to the closest spot of the inspected surface. An This has been shown using an experiment comparing 2D and 3D migrated RES data obtained above steep bedrock beneath Gulkana Glacier, Alaska, which clearly indicated such underestimate and overestimate in bed elevation from the 2D migrated data (Moran et al., 2000). This was also illustrated. Similar results were obtained in a recent study on Mýrdalsjökull Mýrdalsjökull ice cap (in

S-Iceland)- (Magnússon et al., in press) in topographic settings similar to the ESC, using the same radar system as for ESC, where topographic settings and ice thickness are similar (Magnússon et al., in review). There, results applied here. In that study, traced bed reflections from a topographic mapping of the bedrock from parallel profiles separated by 20 m, allowing 3D Kirchhoff migration (e.g. Schneider, 1978) of the RES data, were compared with a previous RES survey adopting 2D migration where majority of the profiles were driven in same direction ~200 m apart, in addition to less dense profiles with different survey directions. The results from the 2D migrated 2D migrated profiles were found to be on average ~10 m higher than the bedrock DEM obtained from the 3D migrated data. The same study showed that when using the 2D migrated data (200 m profile separation) interpolation errors in a bedrock DEM deduced from it were insignificant in comparison to the errors caused by the 2D migration. In the study presented here, where crevasses and the size of the study area do not allow a safe acquisition of data for 3D migration with a reasonable effort, we may expect the 2D migration to introduce a similar bias. This, however, applies both to the reflections from the bedrock and the lake roof shifting both surfaces upwards, hence the effects of this may to a ~~large~~ some extent be cancelled out, when estimating lake thickness and volume. ~~This effect on~~ The resulting bias in the surveyed lake roof elevation should, however, vary between observations and be most prominent when the topography of the lake roof was most uneven in 2017-2018. Assuming that the error in lake volume due the shortcoming of the 2D migration can typically correspond to ~5 m, the average offset in lake thickness would correspond to ~10% error in lake volume.

The RES profiles do not necessarily pass directly above subglacial topographic peaks, which may cause some further distortion in the lake thickness maps and bedrock DEM. In steep areas, these topographic peaks are, however, represented as somewhat lower peaks at the RES profiles close to the actual peaks due to the cross-track reflection explained above. The height of topographic peaks in the lake may therefore be slightly underestimated and their exact planar position is likely somewhere between survey profiles but not directly beneath them as shown in Fig. 6b-h. The denser RES profile network surveyed since 2018 should reduce these errors.

Figure 9 a–b: Cross-section over the centre part of ESC from location A to B (shown in c) revealing bedrock, lake and ice thickness, 4 and 2 months before the jökulhlaups in 2015 (a) and 2018 (b), respectively. The lowering along this cross-section during the subsequent jökulhlaup (derived from Fig. 7) is shown in the upper part of each panel. Note that the y-axis is without vertical exaggeration. **d:** Comparison of lake roof elevation measured with RES, 3 June 2015 (blue numbers and diamonds), and through borehole, 7 June 2015 (red number and x). The borehole location relative to the cross-section A to B is shown in a and c. Red box in c indicates the area shown in d.

4.1.3 Errors in radio wave velocity (c_{gl})

We have a single borehole survey (Fig. 7d9d), which can be used to validate c_{gl} used in the RES processing. The difference between the lake roof elevation at the borehole and nearest point on the profiles is 1 m when using $c_{gl} = 1.68 \times 10^8 \text{ m s}^{-1}$. Taking into the account the mismatch in profile and borehole location (~50 m) and the spatial variability in lake roof elevation from the RES data, it is unlikely that the actual difference between the lake roof elevation at the two locations exceeds 10 m, setting a boundary on the c_{gl} uncertainty, resulting in $c_{gl} = (1.68 \pm 0.05) \times 10^8 \text{ m s}^{-1}$. Further, c_{gl} at this specific location and time may deviate from the average value of c_{gl} in the survey area. We consider it unlikely that c_{gl} exceeds $c_{gl} = 1.70 \times 10^8 \text{ m s}^{-1}$, corresponding to the propagation velocity through dry ice with density 900 kg m^{-3} (Robin et al., 1969). The water content in the temperate ice can, however, reduce c_{gl} significantly (e.g. Smith and Evans, 1972), even below $1.60 \times 10^8 \text{ m s}^{-1}$ (e.g. Murray et al., 2000). Given the value obtained at the borehole, we consider it unlikely that the average value for the survey area corresponds to $c_{gl} < 1.60 \times 10^8 \text{ m s}^{-1}$. If we assume that the spatially averaged value of c_{gl} is approximately the same for all surveys (as suggested by the good comparison of repeated bedrock profile sections), the error in c_{gl} should shift both the lake roof at all times and the bedrock in the same direction proportional to the ice thickness (without a lake above in case of bedrock) except for the relatively small part of the bedrock DEM constrained by borehole measurements (Fig. 6a). Consequently, the error in lake thickness as well as volume due to erroneous c_{gl} should be proportional to the error in the applied value of c_{gl} . If too high applied c_{gl} is used too high, the lake thickness is overestimated and underestimated if applied c_{gl} is too low. Using

Formatted: Font: Not Italic

~~$c_{gl}=1.68 \times 10^8 \text{ m s}^{-1}$~~ For example, if ~~correct~~ the true value of c_{gl} is only $1.60 \times 10^8 \text{ m s}^{-1}$ when value of $1.68 \times 10^8 \text{ m s}^{-1}$ is used, the lake volume would lead to be overestimated by ~5% ~~overestimate on the lake volume and considering the possible %~~. Considering the upper limit, of c_{gl} is $1.70 \times 10^8 \text{ m s}^{-1}$, significant ~~overestimate due to wrong~~ underestimate in lake thickness because of too low applied value of c_{gl} is unlikely. Some of the errors introduced by using too high c_{gl} may be cancelled out by the 2D migration tending to shift reflective surfaces upwards as explained above. ~~For~~ If the value of applied c_{gl} is too low ~~c_{gl}~~ the 2D migration may further exaggerate these errors.

4.1.4 Supraglacial lakes and englacial water bodies

Due to the temporary presence of supraglacial lakes within the ESC (Fig. 5) and englacial water bodies beneath it (Fig. 2h2i) the value of c_{gl} , may differ significantly between some lake roof measurements and bedrock measurements ~~at some locations~~. This may lead, leading to more uncertain larger lake thickness than described above, assuming temporally constant ~~c_{gl}~~ errors at locations where such water bodies appeared. Supraglacial lakes sometimes form within the ESC, probably as a consequence of highly compressive strain rates at the cauldron centre sealing water routes from the glacier surface down to the subglacial lake, resulting in accumulation of surface melt water within the cauldron. It is worth noting that it is possible to trace in 50 MHz radar data (Fig. 5c) a flat water table of an aquifer layer extending from and between the supraglacial lakes. The presence of a supraglacial lake both screens out reflections from the bed beneath the supraglacial lake and reduces c_{gl} , due to increased water content in the media penetrated by the radar. This may affect the traced reflection in areas where the supraglacial lake is not deep enough to fully screen out reflections from the bed or due to high water content close to the glacier surface related to an aquifer layer. This effect was observed in the 2017 RES survey. Then bed reflections outside the subglacial lake, at the edge of the supraglacial lake, appeared up to 20 m below the bedrock elevation observed at same locations in 2019. The lower elevation of the 2017 reflection was attributed to a delay caused by the supraglacial lake and therefore not traced. Around 100 m farther away from the supraglacial lake in 2017, the RES surveys in 2017 and 2019 showed the bed reflections at approximately the same elevation indicating that a delay caused by the aquifer layer extending from the lake in 2017 is insignificant or limited to the shore of the supraglacial lake. The delay caused by a shallow supraglacial lake may result in 10–20 m overestimate in the depth of some of the traced reflections in 2017 and 2018 near the data gaps seen as grey (untraced) profiles near ESC centre in Fig. 4d–e. This may contribute to a corresponding underestimate of the lake thickness for a minority of the traced reflections from the lake roof in 2017 and 2018. It is worth noting that the unusually ~~high~~ undulating lake roof topography ~~of the lake~~ for the same years is likely to cause unusually high upward shift of the lake roof elevation through the previously described limitation of the 2D migration, contributing to an overestimate in lake thickness. It is not certain which of these two counteracting errors influence the derived lake volumes more in 2017 and 2018.

In 2020, englacial features screen out reflection from the bed (Fig. 2h2i) in the same way as the supraglacial lakes in 2017 and 2018. There were no indications in 2020 of snow-covered supraglacial lakes and these features appeared at greater depth than in 2017 and 2018, hence these artefacts in 2020 are attributed to an englacial water layer (sill). Such layers probably need to be several metres thick to produce similar artefacts as the supraglacial lakes, which was apparently the case for a large part of

the ESC centre area in 2020. As a result, reflections from the lake roof could only be traced for a ~~minority~~small part of the profiles crossing the subglacial lake. Fortunately, the lake margin could be mapped allowing an estimate of lake volume, due to the previously mentioned strong relation between the lake volume and area in 2014–2019 (Fig. 6i). When viewing the RES profiles for other years (Fig. 2), we typically see englacial features likely related to water bodies or layers, too thin to screen reflections from the lake roof and the bedrock. There are even indications of such a layer near the centre of the RES profile in Fig. 2e2d corresponding to the time (2015) and the location where the lake roof elevation was directly measured through a borehole (Fig. 749d), showing matching lake roof elevation with $c_{gl}=(1.68\pm0.05)\times10^8$ m s⁻¹. This indicates that despite likely existence of these englacial water bodies they are not causing an excessive delay, and likely affecting all RES surveys in a similar manner in 2014–2019. Likely deviation of c_{gl} in 2020, due to thick englacial water layers, does not affect the corresponding lake volume, as it was estimated using the derived lake area, not by integrating a lake thickness map.

~~The RES surveys in 2014–2020 have revealed supraglacial lakes as temporal features sometimes forming in. The above discussion on likely errors in water volumes due to errors in the 2D migration (<10%) and wrong value of c_{gl} (<5% given that the temporal variability of c_{gl} is small where lake roof/bed reflections could be detected), is in fair agreement with the independent validation (sections 2.5 and 3.1) yielding 10–20% uncertainty in the lake volumes obtained from the RES, particularly if these errors counteract one another. Furthermore, for a lake >100 GI (or >1.5 km²) interpolation errors may have become insignificant in comparison with migration errors by reducing the profile separation down to ~200 m.~~

~~ESC and even though englacial water bodies and layers are generally found beneath the cauldron, it seems that in 2020 these features were more prominent than in other years. This highlights the temporal variability in the englacial and supraglacial hydrology at or beneath ESC. As suggested by Gaidos et al. (2020), the englacial water bodies may play an important role in the triggering of jökulhlaups from the Skaftá cauldrons. A jökulhlaup from WSC in 2015 was most likely triggered via the drilling of a borehole at the cauldron centre, which created a pressure connection between the subglacial lake and an englacial water body above it (Gaidos et al., 2020). Sudden drainage of supraglacial lakes down to the glacier bed (e.g. Das et al., 2008) also highlights these lakes as a potential trigger of jökulhlaups from subglacial lakes, which should be studied further.~~

4.2 The shape of the subglacial lake and its evolution in 2014–2020

The repeated RES surveys in 2014–2020 yield new insight into the shape of the subglacial lake beneath ESC and how it has evolved in recent years. The steep, almost step like, side walls (Fig. 2, 6 and 7) differ from the typical conceptual models of lakes beneath ice cauldrons (e.g. Björnsson, 1988; Einarsson et al., 2017) with the lakes drawn with smooth, approximately parabolic or elliptic, cross-sections. It is also different in form from attempts to approximate the lake shape based on the difference between cauldron surface elevation shortly before and after a jökulhlaup (Einarsson et al., 2017). The observed step-like structures in the lake shape may be an indication of intensive melting at the lake roof and the upper part of the ice walls, with much lower melt rate on the lower part of the ice walls. ~~To fully explain the observed shape of the lake will, however, require extensive modelling that is beyond the scope of this paper. Such a model should ideally combine ice dynamics, the pressure and thermal regime of the lake, the heat exchange between the lake water and ice walls as well as the interaction of~~

~~the geothermal area with the lake, the floating ice above the lake and the surrounding glacier. A model of such complexity may also be required to fully explain the~~ The difference in lake shape before the 2015 and 2018 jökulhlaups (see section 3).
685 ~~Part of the explanation is however probably related to,~~ 2) was at least partly caused by changes in the geothermal area below the ESC. Temperature ~~profile measurements in profiles within~~ the subglacial lakes beneath the Skaftá cauldrons have revealed stable temperatures ~~withof 3–5°C that are mostly independent of lake depth of about 3.5–5°C, allowing, thus enabling~~ effective convection to take place (Jóhannesson et al., 2007; unpublished data at the IMO), ~~and chemical~~. Chemical analyses of the water in WSC lake revealed a component of geothermal fluid of deep origin at ~300°C (Jóhannesson et al., 2007). In 2016–
690 2018 the main vents of the geothermal area, forming centres of a strong convection plumes with peak basal melt directly above, were probably close to the two main maxima in lake thickness observed in all three years at approximately the same location (Fig. 6d–f). These maxima, indicating the locations where most ice had been replaced by meltwater since the 2015 jökulhlaup, were beneath the east side of the cauldron, above the west side of a sharp crater-like depression in the bedrock (section 3.3) and ~800 m farther west, close to the cauldron centre. The same maxima had started forming in 2019 (Fig. 6g) and at least the
695 eastern one had continued growing in 2020 (Fig. 6h). During the period 2010–2015 these two vents in the geothermal system were probably not as powerful as in 2015–2018, explaining the large difference in minimum ice cover thickness for these two periods (260–280 m in 2014–2015 vs. 150–180 m in 2016–2018). A substantial part of the geothermal power in 2010–2015 was likely released by other parts of the geothermal area beneath ESC, which typically are much weaker or dormant, explaining the relatively uniform lake thickness in 2014 and 2015. A ~~Such~~ temporal increase in geothermal activity in 2010–2015 probably
700 occurred near the northern- and southernmost part of the lake in 2014 and 2015. The observed lowering during the jökulhlaup from ESC in 2010 and the evolution of the ESC since the mid 20th century (Gudmundsson et al., 2018) indicates that this behaviour in 2010–2015 was unusual for the geothermal area and the activity in 2015–2018 resembles more the behaviour prior to 2010. Even though the distribution of the released geothermal energy was different for the two periods, the net power of the geothermal area was probably similar, as represented in a similar rate of water accumulation in the lake over time (Fig.
705 9b8b).
Despite the indication of changes in the geothermal area, it should be kept in mind that the lake accumulated water for five years before the jökulhlaup in 2015 compared with three years for the 2018 flood. Some of the difference in lake shape may be due to this. However, the thickening of the ice cover in 2017–2018 (~30 m a⁻¹ at the cauldron centre) and the outward migration of steep ice walls seems too slow to explain the different lake appearance in 2015 compared with 2018. The
710 difference in lake shape may, however, have contributed to the earlier onset of the jökulhlaup in 2018. The shallow lake area outside the steep ice walls in 2018 may be an indication that the glacier outside the walls had started to float up as a consequence of high water pressure in the in subglacial lake. This high subglacial water pressure likely extended somewhat away from the lake through connections in the subglacial drainage system outside of the lake. This may have contributed to the onset of a jökulhlaup two months later.

715 The RES surveys in 2014–2020 have revealed supraglacial lakes as temporal features sometimes forming in the ESC and even though englacial water bodies and layers are generally found beneath the cauldron, it seems that in 2020 these features were

Formatted: Font: 10 pt

more prominent than in other years. This highlights the temporal variability in the englacial and supraglacial hydrology at or beneath ESC. As suggested by Gaidos et al. (2020), the englacial water bodies may play an important role in the triggering of jökulhlaups from the Skaftá cauldrons. A jökulhlaup from WSC in 2015 was most likely triggered via the drilling of a borehole at the cauldron centre, which created a pressure connection between the subglacial lake and an englacial water body above it (Gaidos et al., 2020). Sudden drainage of supraglacial lakes down to the glacier bed (e.g. Das et al., 2008) also highlights these lakes as a potential trigger of jökulhlaups from subglacial lakes, which should be studied further.

4.3 The jökulhlaups in 2015 and 2018

The jökulhlaup in 2015 has been the subject of recently published studies. Ultee et al. (2020) estimated the tensile strength of the glacial ice from the location of crevasse fields formed during the jökulhlaup and Eibl et al. (2020) studied the seismic tremor related to the jökulhlaup and the potential of using seismic array measurements of the tremor for early-warning of subglacial floods. The jökulhlaup in 2018 has not yet received similar attention. The on-line GNSS station, operated by IMO, was running at approximately the same location near the centre of ESC (Fig. 8) during both jökulhlaups. The motion of this station shed an interesting light on the course of events during the jökulhlaups considering the RES measurements of lake shape before the jökulhlaups and the surface lowering during them (Fig. 10-7) during both jökulhlaups.

During the weeks prior to the jökulhlaup the station had been rising relatively fast likely due to rapid inflow melt water from the glacier surface. The rate of uplift was $\sim 0.12 \text{ m d}^{-1}$ and $\sim 0.16 \text{ m d}^{-1}$ the last days before the jökulhlaups in 2015 and 2018, respectively. This may be due to similar rate of inflow; the $\sim 30\%$ larger floating ice cover attributes to lower uplift rate in 2015. The start of the jökulhlaups were observed as the end of these uplift periods in the late evening of 26 September 2015 and 1 August 2018. The start of the jökulhlaup was substantially slower in 2015. The station subsided by $\sim 2 \text{ m}$ during the first day of the jökulhlaup in 2018, while in 2015 it took almost 3 days to reach a similar subsidence (Fig. 10). The slower initial subsidence in 2015 can only partly be due to difference in differences in lake area; this should only between 2015 and 2018 can explain similar the difference as observed in the surface uplift prior to rates before the jökulhlaups but just partly the slower initial subsidence in the 2015 jökulhlaup.

After 2 m subsidence, the GNSS station dropped by 60 m in 2015 and 81 m in 2018 over a period of ~ 40 hours. Then, ~ 4.7 and ~ 2.7 days into the jökulhlaup in 2015 and 2018, respectively (times marked with circles in Fig. 10a), the station subsidence started to decelerate and at the same time an eastward motion started. This was followed by a period of decelerated subsidence lasting for ~ 7 hours in 2015. This period probably corresponds to the time when a “keel” at the bottom of the floating ice cover clashes with the bedrock beneath or close to the station. The net subsidence of 68 m at the end of this period (marked with grey triangle in Fig. 10a) fits well with the 67 m lake thickness obtained at the GNSS station as the difference between the bedrock DEM (the GNSS station was located less than 80 m from boreholes where the bedrock elevation was measured directly) and the traced lake roof elevation in June 2015. In 2018, the period of decelerating subsidence lasted for a day. The 94.5 m net subsidence by the end of this period (marked with black triangle in Fig. 10a) is substantially less than the 140 m lake thickness obtained 50 m north of the station in 2018. This lake thickness is, however, obtained at the side of a steep up-

750 doming of the lake roof. The traced lake roof elevation at this location in 2018, was therefore sensitive to the limitation of the
 2D migration (section 4.1.2) and likely corresponds to a reflection from the lake roof 100–200 m farther NNE-(traced reflection
 from RES profile surveyed with ESE direction).
 It is worth noting that during the main subsidence period in 2018, a sudden temporal deceleration occurred in the subsidence
 as well as in ice flow direction after only 15 m subsidence ~1.6 days into the jökulhlaup (marked with star in Fig. 10a). Such
 755 a deceleration is not observed in 2015.-It and may be related to caused by floating ice, atop of the 10–30 m thick water layer
 observed around the main water chamber in 2018. After a subsidence of only 15 m this floating ice may have hit, moving
 against the bedrock only a few hundred metres south of the GNSS station. Due to the Whilst a supraglacial lake, the closest
 traced reflections in June 2018 inhibited complete mapping south of the GNSS station were, traced reflections from RES data
 450 m away. The south of the station indicate grounded ice or lake roof only few metres above the bedrock.

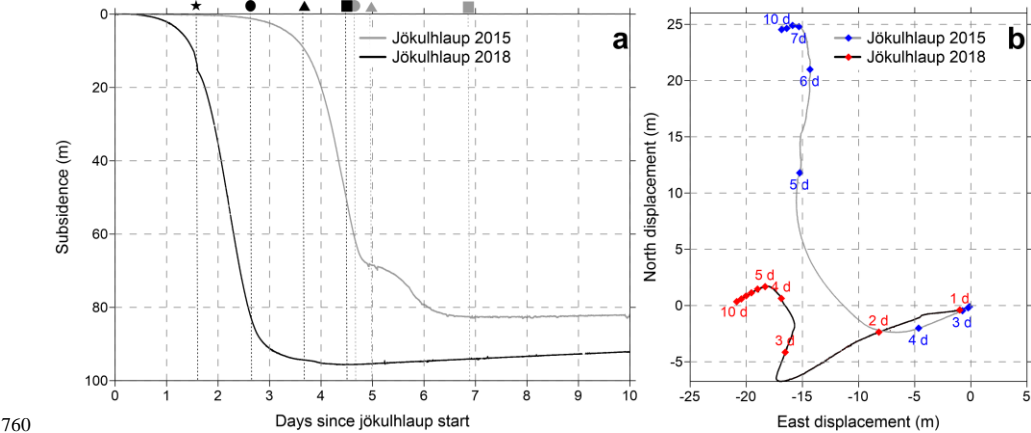

Figure 10 a: The subsidence of the GNSS station in ESC (exact location shown in Fig. 87) during the jökulhlaups in 2015 (grey profile) and 2018 (black). The times marked with forms (star, circles, triangles and squares) are mark timestamps of events discussed in the section 4.3.
b: A planar view showing the horizontal track of the station during the jökulhlaup relative to its position at the onset of the jökulhlaup. Blue and red diamonds show positions of the station at 24 h intervals during the 2015 and 2018 jökulhlaups, respectively.

765 After the period of decelerating subsidence in the late stage of the jökulhlaups, the subsidence temporally sped up again in
 both jökulhlaups. The speed-up was quite significant in 2015 but only minor in 2018. The station reached a total subsidence
 of 82.6 m in ~6.9 days during the 2015 jökulhlaup (grey square in Fig. 10a) and 95.6 m in ~4.5 days, three years later (black
 square in Fig. 10a). The horizontal motion of the station continued to decelerate and change direction for a bit more than a day
 during both jökulhlaups. This probably marks the jökulhlaup terminations ~8 and ~6 days after they started in 2015 and 2018,
 770 respectively. Lake water was probably still draining slowly from beneath the areas where the lake was thickest both in 2015
 and 2018, east and west of the GNSS station, beyond the period of subsidence as recorded by the GNSS station, during the
 period of gradual slow-down in horizontal motion. At the end of the 2015 jökulhlaup, the station was located on a relatively

steep northward sloping glacier surface (Fig. 8e7e). The lowering during the final phase of this jökulhlaup, when the station is moving rapidly in north direction (Fig. 10b), is therefore, to some extent ice motion parallel to the glacier surface slope. The station lowered by 15.5 m and moved by similar distance northwards during this period. The ice surface geometry near the station ~~near~~ in the late stage of the jökulhlaup may favour local thinning due to strong tensile strain rates, which may also partly explain the net thinning of the ice obtained near the station in 2015 (Fig. 8e7e). In 2018, the GNSS station ended at a relatively flat area, resulting in much less subsidence and horizontal motion during the final phase of the jökulhlaup.

The motion of the GNSS station during the jökulhlaups gives insight into the scale of the events in terms of ice movements, which further helps understanding the difference between obtained lake thickness prior to the jökulhlaups and the surface lowering during the jökulhlaups (Fig. 87). In addition to the subsidence >70 m in a single day in 2018 (>50 m in 2015), the maximum horizontal velocity of the station was above 10 m d⁻¹ in 2018 and around 20 m d⁻¹ in 2015. The net horizontal displacement during the jökulhlaup, which did not follow a straight line, was approximately 30 m in 2015 and 20 m in 2018 (Fig. 10b). We may expect that the horizontal displacement at the location of the station at the cauldron centre ~~isto be~~ substantially less than near the sides of the cauldron where the ice~~_~~flux towards the cauldron centre is highest. There, the net horizontal displacement may exceed 100 m. With this in mind, it is easier to understand how thickening of ice at ~~a~~ given location may be up to 170 m as estimated in 2018 (Fig. 8f7f). The 100–200 m high walls of the main water chamber in 2018 with slopes sometimes exceeding 60° (Fig. 7b9b) possibly moving many tens of metres inwards, may therefore produce >100 m increase in apparent ice thickness near the pre-jökulhlaup ice walls. The extension of the thickening area into the main crevasse field at the north side of ESC in 2018 (Fig. 8f7f) is probably an expression of ice dynamics of this kind. Even though the ice in this area became thicker it suffered high tensile strain rates causing the crevasse formation. This effect is, however, expected to be largest in the east side of the cauldron where the estimated ice thickening is by far greatest (Fig. 8e7e–f). In this area, we observe the steepest and highest ice walls of the lake prior to the jökulhlaups, particularly in 2018. This was also the area surrounded with the largest crevasses in 2018 (Fig. 4e1d). Additionally, the bedrock at this location is steeply inclined towards a deep bedrock depression beneath the thickest part of the lake (Fig. 6–7). This may enhance sliding of the ice towards the depression centre during the jökulhlaup; inward sliding of the ice walls would produce stronger apparent thickening than if these ice walls would only be tilted inwards without sliding along the bed.

When the net inward horizontal motion ~~may decrease~~decreases from ~100 m to zero over a distance of few hundred meters, we may expect that thickening of the ice caused by compressional straining during the jökulhlaups was several tens of meters, comparable with the ice thinning observed outside the lake (Fig. 8e7e–f) by tensile straining. The high compressional strain rates are evident in compressional ridges that are formed near the centre of the cauldron during jökulhlaups (Fig. 4e1f) as well as the high uplift rate of the GNSS station after the jökulhlaups. In 2018, the uplift rate of the station the first days after the jökulhlaup was ~0.7 m d⁻¹ (Fig. 10a). When the surface elevation of the cauldron was mapped on 9 August, the station had risen by almost 3 m from its lowest elevation (on 5 August), likely due to post-jökulhlaup ice thickening caused by compressional straining. The post-jökulhlaup strain rates are expected to be much lower than during the jökulhlaups; the horizontal velocity of the GNSS station during them was an order of magnitude higher than after they ended.

The data sets obtained during the jökulhlaups in 2015 and 2018, could be further used to extract information about the mechanical properties of glacial ice, such as parameters describing viscous and elastic deformation and fracture strength. Interpretation of the available data about ice-surface lowering and the geometry of the ice shelf and subglacial water body in terms of mechanical properties requires the coupled modelling of the dynamics of the ice shelf and outflow from and the water pressure in the subglacial lake. For modelling the collapse of the cauldron during these jökulhlaups, the RES observations define the shape of the lake at the start of drainage and the subsidence of the GNSS station can be used as a constraint on the water outflow from the lake during the jökulhlaup. The time-dependent pressure in the lake is required as a boundary condition to describe to what extent the weight of the overlying ice is supported by stresses in the ice and to what extent the ice floats on the subglacial water body. The result of such a modelling experiment, mimicking the observed elevation changes and crevasse formation, may advance the modelling of ice dynamics during extreme strain rates, such as for glacier calving. Such a model, which may require a particle-based model of glacier dynamics to fully include the brittle behaviour of the glacier ice (Áström et al., 2013), could also be used to estimate temporal variations in the lake water pressure during the jökulhlaup. This might answer whether sudden temporary drops of water pressure in the lake may trigger lowering of pressure within the uppermost part of the geothermal system beneath the ESC, considered ~~as an explanation~~ the cause of powerful low frequency seismic tremor pulses (Eibl et al., 2020; Guðmundsson et al., 2013b) that have often been observed near the end of jökulhlaups from the Skaftá cauldrons.

5 Conclusions

The ~~RES data presented results~~ from ~~repeat RES surveys carried out annually over~~ the Eastern Skaftá Cauldron (ESC) in 2014–2020, for quantitative monitoring of the subglacial lake beneath the cauldron, and ~~a comparison~~ the validation with surface lowering during jökulhlaups, yielding independent measurements ~~on the lake volume, shows that RES can be used for quantitative monitoring of the of the lake volume,~~ demonstrates the applicability of RES for this purpose. No other type of measurements ~~have~~ has provided such volume estimates for ESC prior to ~~jökulhaups, ajökulhlaups,~~ key knowledge for assessing the hazard of a potential jökulhlaup. The validation indicates an error of <20% in 2015 and <10% in 2018 for the lake volumes from RES. The smaller error in 2018 was likely due to the reduction in the RES profile separation from ~400 m to ~200 m. It is, however, not certain whether reducing the profile separation more would reduce the volume errors further due to the limitations of the 2D migration applied. Further improvement may require much denser RES profiles, allowing 3D migration, which is not achievable with a reasonable effort for the ESC, but can be applied for studying water accumulation beneath smaller ice cauldrons.

The study presents new insight into the shape and the development of a subglacial lake beneath ~~an ice cauldrons~~ cauldron, maintained by ~~subglacial~~ geothermal activity, as well as the complex ~~hydrologic~~ hydrology systems related to these cauldrons, not only beneath the ice but also within ~~it~~ and at its surface. In addition, the study provides a unique view on how the shape of

a subglacial lake beneath ice cauldrons is reflected in the lowering of their surface during jökulhlaups. These new observations, therefore, provide ~~interesting~~ study opportunities related to ice cauldrons, including ~~e.g.~~ studies on:

- ~~i)~~ i) The interaction between the geothermal area, the lake and the ice, as reflected in the shape and development of the lake.
- ~~ii)~~ ii) The triggering mechanism of jökulhlaups from ~~lakes~~ beneath ice cauldrons.
- ~~iii)~~ iii) The ice dynamics and processes taking place within and beneath ice cauldrons during large jökulhlaups.

Data and code availability

The authors declare that all code and data presented in the paper are available upon request except the TanDEM-X data provided by DLR, which is restricted to the users defined by the project NTI_BIST6868.

Author contributions

EM and FP designed the research study and methods, carried out the all the low frequency RES-surveys as well as all processing related to these surveys. MTG and ThH were responsible for the survey and processing of the radar altimetry data acquired in August 2018. CR processed the TanDEM-X DEMs used in the study. BGÓ and TJ were responsible for operating the GNSS stations during the jökulhlaups in 2015 and 2018. ThTh lead the drilling into the subglacial lake beneath ~~ESKESC~~ in June 2015 and ES was responsible for the survey with the 50 MHz radar in June 2017. EM made all figures except Figure 79, which ~~TH~~ was designed by ThH. EM prepared the manuscript with contributions from all co-authors.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgements

This work was funded by the Icelandic Research fund of Rannís within the project Katla Kalda (project nr. 163391) and the Icelandic Avalanche and Landslide Fund through the volcanic hazard assessment program GOSVÁ. TanDEM-X data was provided by DLR through the project NTI_BIST6868. Landsat-8 image courtesy of the U.S. Geological Survey. Copernicus Sentinel-2 data from 2018 was processed by ESA. Radar altimetry data was acquired with the survey aircraft TF-FMS of the Icelandic Aviation Service (Isavia). All the RES-surveys were carried out during the annual field trips of the Iceland Glaciological Society (JÖRFÍ) on Vatnajökull. Sveinbjörn Steinþórsson, Ágúst Þór Gunnlaugsson, Vilhjálmur S. Kjartansson,

865 Bergur H. Bergsson and Bergur Einarsson as well as JÖRFÍ volunteers are thanked for their work during field trips. We thank
two anonymous reviewers for constructive reviews, which resulted in significant improvements of the paper.
