Abstract. The Thwaites Eastern Ice Shelf (TEIS) buttresses the eastern grounded portion of Thwaites Glacier through contact with a pinning point at its seaward limit. Loss of this ice shelf will promote further acceleration of Thwaites Glacier. Understanding the dynamic controls and structural integrity of the TEIS is therefore important to estimating Thwaites' future sea-level contribution. We present a ~20-year record of change on the TEIS that reveals the dynamic controls governing the ice shelf's past behavior and ongoing evolution. We derived ice velocities from MODIS and Sentinel-1 image data using feature tracking and speckle tracking, respectively, and combined these records with ITS_LIVE and GOLIVE velocity products from Landsat 7 and 8. In addition, we estimated surface lowering and basal melt rates using the REMA DEM in comparison to ICESat and ICESat-2 altimetry. Early in the record, TEIS flow dynamics were strongly controlled by the neighboring Thwaites Western Ice Tongue (TWIT). Flow patterns on the TEIS changed following the disintegration of the TWIT in ~2008, with a new divergence in ice flow developing around the pinning point at its seaward limit. Simultaneously, the TEIS developed new rifting that extends from the shear zone upstream of the ice rise and increased strain concentration within this shear zone. As these horizontal changes occurred, sustained thinning driven by basal melt reduced ice thickness, particularly near the grounding line and in the shear zone area upstream of the pinning point. This evidence of weakening at a rapid pace suggests that the TEIS is likely to fully destabilize in the next few decades, leading to further acceleration of Thwaites Glacier.

1 Introduction

Thwaites Glacier in West Antarctica holds the most important control on global sea-level rise over the next few centuries (Scambos et al., 2017). The broad causes and implications of the destabilization of Thwaites have been understood for decades: increased delivery of warm modified Circumpolar Deep Water (mCDW) to grounding zones triggers retreat of an ice sheet grounded well below sea level (e.g. Holland et al., 2019), leading to dynamic instability and greatly accelerated ice discharge into the ocean (Hughes, 1981; Mercer, 1978, Weertman, 1974). Recent evidence suggests that the predicted irreversible retreat of Thwaites Glacier is already underway (Joughin et al., 2014; Rignot et al., 2014). However, knowing the details of the timing, magnitude, and pace of the collapse of Thwaites are essential for more detailed forecasting of its sea-level contribution.

To understand these changes, we need to define both the oceanic forcing responsible for initiating retreat and the dynamic response that governs the inherent instability of the system. At the interface of this forcing and dynamic response are the floating ice components that form the seaward terminus of Thwaites Glacier. Because this ice interacts directly with ocean water, changes in its velocity and thickness may reveal clues about ocean forcing (e.g. MacGregor et al., 2012; Miles et al., 2020; Pritchard et al., 2012). Ice shelves and ice tongues also actively impact the dynamic stability of the system, as contact with the seafloor and embayment walls transmits backstress to grounded ice and slows ice flow and retreat (e.g. Dupont and Alley, 2005; MacGregor et al., 2012; Reese et al., 2017). Changes in ice-shelf dynamics and surface features may therefore signal fundamental imbalances in the system that can trigger rapid future change.

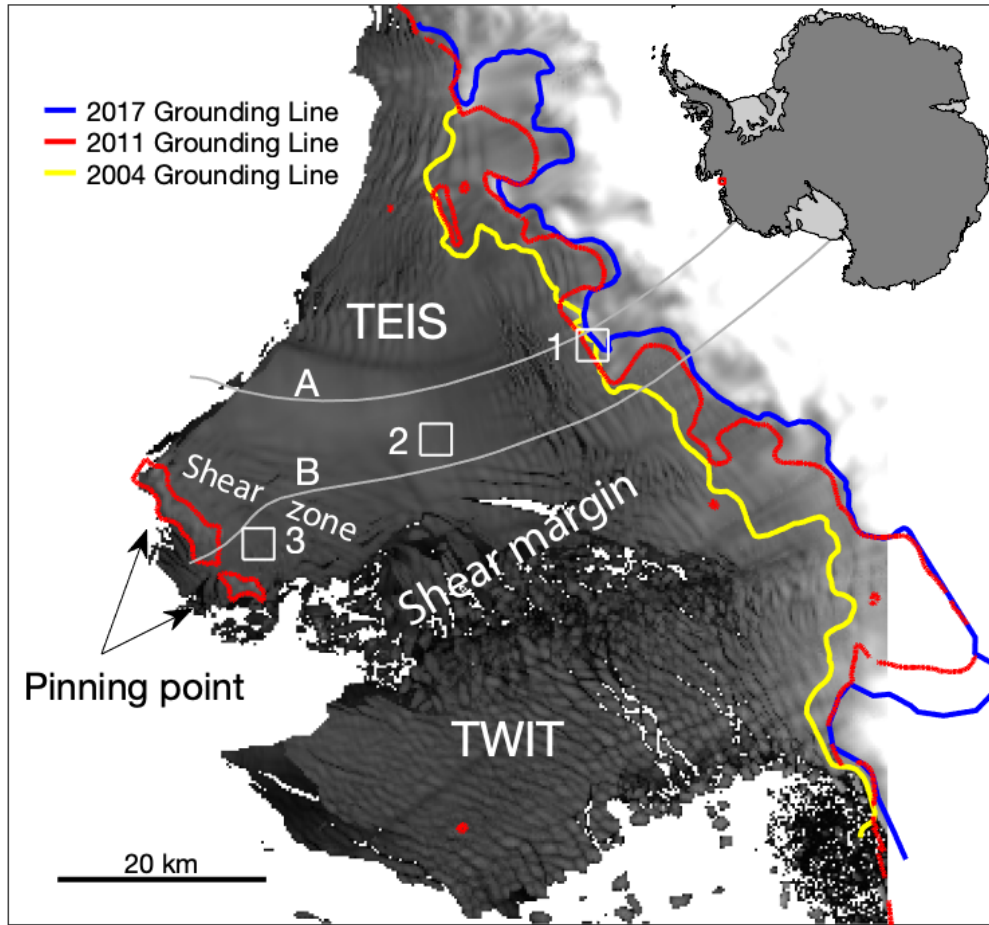
Thwaites Glacier has two floating ice areas: the Thwaites Western Ice Tongue (TWIT), and the Thwaites Eastern Ice Shelf (TEIS; Figure 1). Most of the ice discharge from Thwaites passes through a fast-flowing channel that feeds the TWIT, which is an unconfined floating ice tongue that has largely disintegrated in recent years. Until the early 2000s, the TWIT was grounded on a subsea ridge near the ice edge (Rignot, 2001), which was likely the site of the main grounding line for this section of the ice shelf decades to centuries ago (Tinto and Bell, 2011). By 2009, the TWIT had largely lost contact with this pinning point (MacGregor et al., 2012; Tinto and Bell, 2011), although some grounding of the TWIT on the subsea ridge may have occurred intermittently for several more years (Miles et al., 2020).


Figure 1: Location map. The Thwaites Eastern Ice Shelf (TEIS) and Thwaites Western Ice Tongue (TWIT) are labelled. We also indicate the "pinning point," the "shear zone" upstream of the pinning point, and the "shear margin" between the TEIS and the TWIT, which are terms discussed in the text. Three 3 km x 3 km sites of interest are shown, which are referred to in the text as the "grounding zone" (site 1), "mid-shelf" (site 2) and "pinning point" (site 3) areas. Data from these sites are shown in Figures 2 and 5. Flowlines based on 2015-2020 velocities, labelled A and B, are represented in Hovmöller diagrams in Figures 3 and 6. Grounding lines are from approximately 2004 (Bindschadler et al., 2011), 2011 (Rignot et al. 2011), and 2017 (Milillo et al., 2019). Figure created using the Antarctic Mapping Tools for Matlab (Greene et al. 2017).

Variability in TWIT velocity and structural integrity has been documented in detail (Miles et al., 2020; Mouginot et al., 2014). The last 20 years included periods of relatively stable velocity, which were accompanied by a
70   strengthening of the shear margin between the TWIT and the TEIS. However, the more recent record has been dominated by periods of instability, with increasing velocities, extremely rapid ice-edge retreat, and a loss of coherence in the TWIT/TEIS shear margin (Miles et al., 2020; Mouginot et al., 2014). As the ice tongue nearly completely detached starting around 2008, the TWIT is unlikely to return to a stable configuration with a strong TWIT/TEIS shear margin.

75

The large changes observed on the TWIT have also significantly impacted the behaviour of the TEIS (Miles et al., 2020; Mouginot et al., 2014), which maintains a very different configuration than the TWIT. The same ridge that pinned the TWIT to the seafloor in past decades is responsible for a large ice rumple that confines the seaward limit of the TEIS (Tinto and Bell, 2011). As this ice rumple provides significant buttressing to the grounded ice
80   upstream (Fürst et al., 2016; Reese et al., 2017), we will refer to it as a pinning point. This pinning point is at least partially responsible for the slower velocities and more stable calving-front positions of the TEIS as compared to the TWIT. The loss of this buttressing due to disintegration of the TEIS would therefore likely cause a step increase in ice discharge through the eastern portion of the ice stream, leading to ocean circulation changes and a response in the pace of grounding-line retreat.

85   In this study, we present detailed records from the last two decades of dynamic change on the TEIS. Patterns of ice-shelf speed, flow direction, and surface strain rates derived from optical and radar imagery are analysed to understand the dynamic trends and the forcings that control those trends. Data from satellite-derived DEMs and laser altimetry reveal spatial patterns of thinning across the ice shelf, which suggest details of decadal-scale ocean forcing. With the additional context of surface-feature change, our data suggest that the TEIS has exhibited
90   evidence of destabilization over the last two decades that is likely to continue to progress in the future.

2 Data and methods

2.1 Velocity and strain-rate data and methods

We assembled two velocity records for this analysis: a long-term (20-year) record of two-year composites of velocity maps, temporally centred on summers and derived from MODIS, Landsat-7, and Landsat-8 optical image
95   pairs; and a short-term (five-year) record of seasonal average velocity derived from MODIS, Landsat-8, and Sentinel-1 radar imagery. All velocities were generated by feature or speckle tracking. We also used the calculated velocities to derive flow direction and strain-rate component maps.

MODIS-based velocity estimates used in this study were derived using the Python-based image cross-correlation

100   software PyCorr (Fahnestock et al., 2016). MODIS images are available at 250 m spatial resolution through the NSIDC Ice Shelf Image Archive (Scambos et al., 1996) from 2000-2019, and these images are the main source of the velocity record presented here from 2000-2013. MODIS correlations were limited to image pairs with a separation of at least 50 days, as the low spatial resolution requires large feature displacements for accurate measurement. This low spatial resolution also means that MODIS correlations are inaccurate above the grounding

105   line, where surface features that move at the ice flow velocity are too small for MODIS to track accurately. In these grounded areas, the features with strong correlation are primarily the surface undulations arising from ice interaction with bedrock, yielding incorrect near-zero speeds. On floating ice, MODIS successfully correlates larger crevasse features, basal crevasses, and rifts, and results match very closely with velocities estimated from other sources.

110

When available during the 2000-2013 time period, we have also utilized velocities derived from Landsat-7 available through the ITS_LIVE global ice velocity project (Gardner et al., 2019). These data are severely limited by the scan-line correction malfunction that caused significant data loss in Landsat-7 images after 2003, and the relatively low radiometric resolution makes successful velocity correlations very limited. We have, however,

115   included all available correlations in our record. In addition, we investigated available images from ASTER, but very few cloud-free images are available during this time period and most correlations from those images were unsuccessful, so this dataset is not included. We were also unable to include published annual velocity grids derived from SAR (Mouginot et al. 2017) because they have a lower spatial resolution than our record and lack significant spatial coverage in this area for most years between 2000 and 2013. Therefore, MODIS-derived velocity

120   data provide most of the measurements in our record before 2013.

Data resolution and availability improve significantly in 2013, when Landsat-8 launched. Every available Landsat-8 image pair is processed with PyCorr and distributed at 300 m resolution as part of the GOLIVE project (Scambos et al., 2016). We used all available correlations for 10 Landsat-8 paths/rows that overlap the TEIS. Because

125   Landsat-8 has a higher spatial and radiometric resolution than MODIS and a higher radiometric resolution than Landsat-7 (15 m pixels and 12-bit digitization), correlations are successful with shorter time separations. In areas with fewer large surface features, the algorithm applied to Landsat-8 image pairs can detect the displacement of persistent sastrugi fields on the ice-shelf surface.

130   For both MODIS and Landsat-8, PyCorr was used to produce velocity correlations as well as images that describe the correlation strength for each pixel and the difference in correlation strength between successful correlations

and neighbouring options. Velocity output images were filtered using thresholds on these parameters, which were individually tuned according to the noise in each composite velocity grid. The results were smoothed using a 3x3 median filter to remove spurious correlations.

135

Despite having multiple data sources, data gaps are common early in our 20-year record. We therefore produced each annual image by combining two full years of data centred on a summer season. Velocity correlations for each time period were spatially interpolated to a common grid at 500 m resolution. The images were then stacked, and a derived image for each time period was produced by taking the median value of the stack of values at each grid

140 cell. Small data gaps (<~5 pixels in any dimension) were filled using bilinear interpolation. The x- and y-component velocity images were then used to calculate flow directions, as well as flow-oriented longitudinal, transverse, and shear strain rates. These strain rates were calculated using a logarithmic formulation and a 5 km length scale, which is approximately consistent with viscous processes (Alley et al., 2018).

145 We also produced velocity grids with seasonal temporal resolution for the last ~5 years of the record, with winter velocity values provided by radar imagery. Sentinel-1 radar imagery is available starting in late 2014, with more consistent coverage available from September 2016 with the Launch of Sentinel-1B. Velocities from Sentinel-1 were derived using feature tracking between 12-day Interferometric Wide (IW) image pairs from 2014 to September 2016 and 6-day and 12-day image pairs between September 2016 and December 2020. We used feature

150 tracking patch sizes of 416x128 pixels (~1-km square on the ground) and sampled every 50x10 pixels (~100 m on the ground). Feature tracking uses the Gamma Software and utilises physical features on the ice (crevasses, icebergs etc.) as well as speckle patterns where the images are phase-coherent (speckle tracking). We corrected for tides using the CATS2008 tide model (Padman et al., 2002). Sentinel-1 velocity grids were filtered using the signal-to-noise ratio and an area-based noise filter and combined to produce mean quarterly velocity maps. We

155 utilize a record in this study derived only from Sentinel-1 imagery starting in 2014 that provides high-spatial-resolution information despite data gaps. We also produced a smoother but lower-resolution combined 5-year record with MODIS and Landsat-8 correlations. Like our 20-year record, this record was gridded at 500 m and used to calculate strain rates on a 5 km length scale.

160 Uncertainty in velocity estimates comes from two main sources: errors in geolocation of the satellite imagery and errors in cross-correlation. Cross-correlation errors in PyCorr are expected to be less than 0.1 pixels (Fahnestock et al., 2016), which is 25 m for MODIS imagery and 1.5 m for Landsat-8. MODIS geolocation accuracy is better than 50 m (Wolfe et al., 2002), and Landsat-8 geolocation accuracy is better than 15 m (Fahnestock et al., 2016). MODIS imagery was correlated with no less than 50-day separations between images, with most separations

165 between ~60 and 200 days. This yields a total maximum error estimate for individual image-pairs of ~450 ma⁻¹ on

an ice shelf flowing at ~750 ma⁻¹. Landsat-8 error estimation with a minimum of 16-day separations (most were

16 to 128 days) yields an individual image-pair error of ~400 ma⁻¹. By a similar analysis, errors in individual

Sentinel-1 velocities are estimated to be less than 100 ma⁻¹. These are maximum error values. More typical

geolocation errors are half of the stated maximums, and with ~100 day separations, errors for a single velocity pair

170 are ~90 ma⁻¹ and 25 ma⁻¹ for MODIS and Landsat, respectively.

In addition, these error estimates refer to individual image pairs, and our composite products stack as many image

pairs as were available during each time period, taking the median value for each pixel. Assuming a normal

distribution of error, this significantly increases the accuracy and precision of our velocity estimates. To get an

175 empirical estimate of our measurement uncertainties, we calculated the uncertainty as:

$$\delta = \frac{st}{\sqrt{n-1}} \qquad\qquad (1)$$

Where δ is the uncertainty, s is the standard deviation of the pixel stack, t is calculated from the standard t-

distribution, and n is the number of pixels in the stack. We used standard error propagation principles to estimate

the total uncertainty in derived flow directions and strain rate records, which are shown as error bars in Figures 2

180 and 5. The signals we discuss in this study fall well outside these error bars.

2.2 Surface elevation data

Surface-elevation change was calculated using a combination of photogrammetry-derived digital elevation models

(DEMs) and laser altimetry data. The Reference Elevation Model of Antarctica (REMA; Howat et al. 2019) was

185 created using sub-meter-scale DEM strips derived from GeoEye and Worldview satellite imagery. We used a tile

from the 8-m mosaicked product, which includes data from the 2013-2014 summer season in the TEIS area. The

DEM strips used to create this product were vertically referenced using Cryosat-2 altimetry data, which were

projected using area-averaged thinning rates to the time that each strip was collected. Estimated elevation errors

provided with the REMA tile, which take into account DEM strip creation errors and vertical referencing, are on

190 average ± 6 m in this tile. However, the altimetry data used for referencing were not corrected for tides. Tidal

amplitude in this region is approximately ± 1 m (Padman et al., 2002). As errors in DEM strip creation and vertical

referencing are uncorrelated with tides, our total estimated vertical error associated with the REMA tile is

approximately ± 6 m. While this is a significant absolute error, REMA strips have been registered vertically where

Cryosat-2 data are available, and nearby strips have then been referenced to each other. We therefore expect the

195 error in REMA to be strongly spatially correlated, particularly within mosaicked tiles, allowing us to analyse

spatial patterns with more confidence than absolute changes. We expect to find the largest errors at strip boundaries where blending techniques have been used to match DEM strip edges (Howat et al. 2019).

The ICESat and ICESat-2 data were corrected following Smith et al. (2020) and Paolo et al. (2016). Data corrections were performed using the Python-based Cryosphere Altimetry Processing Toolkit (Captoolkit; https://github.com/fspaolo/captoolkit). All ICESat data were downloaded from the GLA12 release 634 data product (Zwally et al. 2014). We applied corrections for the Gaussian-centroid offset, as well as corrections for inter-mission laser bias and signal saturation (Borsa et al., 2014). In addition, we applied filters based on several data quality flags (we retained points with use_flg = 0, sat_corr_flg < 3, att_flg =\= 0, and num_pk =1), and retained only points unaffected by clouds (cloud_flg = 0). We converted all measurements to the WGS84 ellipsoid. ICESat-2 data were provided as part of the ATL06 land-ice data release (Smith et al., 2019), which gives surface elevations with respect to the WGS84 ellipsoid. Data were removed if they were flagged by the provided quality summary flag (atl06_quality_summary), and points were removed that were in segments with high along-track variability or that listed unrealistic surface heights (which are most likely the result of atmospheric scattering). For both datasets, we removed the ocean tide and ocean loading corrections applied to the data in the release. We then re-tided the data with ocean tides derived from the Circum-Antarctic Tidal Simulation (CATS2008; Padman et al., 2008), load tides from the fully global barotropic assimilation model (TPXO9) from Oregon State University developed by (Egbert and Erofeeva, 2002), and accounted for the inverse barometric effect (IBE; Dorandeu and Traon, 1999; Mathers, 2002) using sea-level pressure data from the ERA-5 reanalysis (Bell et al., 2020). ICESat and ICESat-2 points are expected to have an accuracy better than 5 cm with a precision better than 15 cm (Brunt et al., 2019).

As ocean tides, ocean loading, and IBE are generated by ocean processes, we did not apply these corrections to grounded pixels. The TEIS has experienced extensive grounding-line retreat during the past two decades. While annual estimates of grounding-line location are unavailable, we were able to obtain three grounding-line products that were used to determine floating areas in this analysis. For the ICESat data, we used the continent-wide grounding line estimated by Bindschadler et al. (2011). This grounding line was derived using Landsat-7 data from 1999-2003 and ICESat data from 2003-2008. For our ICESat-2 data, we used the InSAR-derived 2017 grounding line location from Millillo et al. (2019), which was the most recent estimate available to us. Neither dataset includes the grounding line for the pinning point at the seaward limit of the TEIS. We therefore used a 2011 grounding line from the MEaSUREs dataset (Rignot et al., 2016) to estimate the grounded area for both DEMs. We combined this grounding line information with BedMachine ice thickness (Morlighem et al., 2020) to create an "alpha" map for each time period (Han and Lee, 2014; Wild et al., 2019), which shows whether each pixel is freely-floating (a

value of 100%) or fully grounded (a value of 0%). These maps of tide-deflection ratio were calculated with a two-dimensional elastic finite-element model, as formulated by Walker et al. (2013). Corrections for ocean and load tides and IBE were then scaled according to the percentage indicated in the alpha map before being applied to the ICESat and ICESat-2 data. We assumed that solid Earth displacement due to ocean tidal loading was negligible above the grounding line. Comparisons of data from in situ GPS units deployed since the 2019-2020 season and the CATS2008 tide model, with load tides and IBE included, show an error of ± 17 cm in the TEIS region.

Overall, we estimated the error in the surface elevation change data to be the sum of the errors in the individual measurements divided by the time difference between the measurements, which yields a total average error of approximately ± 1.25 m/yr for the surface lowering estimate between REMA and ICESat-2, and ± 0.75 m/year for the estimate between ICESat and REMA. We note broad agreement in the thinning patterns between the ICESat/REMA and REMA/ICESat-2 estimates, which suggests that the actual error is typically below the change signal, and smaller than the estimates given here. We expect the largest errors to be found in areas where mosaicked REMA strips join, with more reliable estimates within the boundaries of individual REMA strips.

2.3 Lagrangian estimates of thickness change and basal melt

Measurements of surface lowering and ice-thickness change, along with derived estimates of ice-shelf thinning and basal melt rates, are most easily calculated from altimetry data using an Eulerian framework, which considers measurements in a fixed reference frame relative to the geoid. This approach often yields large positive and negative values that are the result of advection of ice of differing thickness, rather than representing true change in the thickness of the ice shelf over time. We therefore used a Lagrangian framework, which calculates change in a reference frame moving with ice flow.

To calculate Lagrangian ice-parcel flow paths, we used our annual velocity composites to migrate the altimetry points from ICESat and ICESat-2 to the locations the ice parcels would have been when the REMA data were collected. Velocity vector components were interpolated in both space (using bilinear interpolation) and time (using linear interpolation) to match the time and location the altimetry points were collected. The points were then allowed to move according to the interpolated velocity components for a time step of 10 days, at which point interpolation was repeated. This process was continued until the points reached the same time that the REMA

pixels were collected. ICESat and ICESat-2 elevation values were smoothed along track using a moving average over 500 m to match the resolution of the velocity measurements.

We assessed both change in surface elevation and change in ice thickness. Lagrangian surface-elevation change (Dh/Dt) is valid on both grounded and floating ice, and was found by subtracting the surface height at the earlier
260   time from the surface height at the later time at migrated altimetry point locations. Ice thickness and basal melt rates were estimated using an assumption of hydrostatic equilibrium. For these calculations, we used the alpha maps described above to remove any ICESat or ICESat-2 points outside of hydrostatic equilibrium before Lagrangian trajectory calculations. Following parcel movement, we removed any points that ended outside of hydrostatic equilibrium using an alpha map based on the MEaSUREs 2011 grounding line (Rignot et al., 2011).
265   ICESat, ICESat-2, and REMA elevations were converted to ice thickness using (Jenkins and Doake, 1991):

$$Z_s = \left(1 - \frac{\rho_i}{\rho_w}\right) H + \left(\frac{\rho_i}{\rho_w}\right) h_a \qquad (2)$$

where Z_s is the surface elevation, ρ_i is the density of ice (917 kg/m3), ρ_w is the density of seawater (1026 kg/m3), H is the ice thickness, and h_a is equivalent firn-air column thickness. We obtained a spatially variable estimate of h_a from Bedmachine (Morlighem et al. 2020), and estimated temporal variability in h_a using a one-dimensional
270   firn model (SNOWPACK; Keenan et al., 2021 accepted) that is adapted for Antarctic climate conditions and forced by MERRA-2 reanalysis (Gelaro et al., 2017). Using SNOWPACK, we simulated the evolution of a 100-m firn column at 75°S, 106.25°W from January 1, 1980 to December 31, 2019. The model outputs % air in each firn layer which is multiplied by layer thickness (m) and summed across all layers to obtain h_a. Variability over this time period is a maximum of 1 m, which is taken to be the uncertainty in h_a.

275   To calculate basal melt rates, we used solid-ice-equivalent column heights, which were found by subtracting the firn-air column thickness from the total thickness. The Lagrangian thickness change of a parcel (DH/Dt) was calculated by differencing the ice thicknesses at migrated altimetry point locations. We then calculated basal melt rate ($\dot{m}_b$) using mass conservation (Jenkins and Doake, 1991):

$$\frac{DH}{Dt} + H(\dot{\epsilon}_{lon} + \dot{\epsilon}_{trans}) = \dot{m}_s + \dot{m}_b \qquad (3)$$

280   Where $\dot{\epsilon}_{lon}$ and $\dot{\epsilon}_{trans}$ are time-averaged longitudinal and transverse strain rates. The surface mass balance $\dot{m}_s$ was estimated using MERRA-2 atmospheric reanalysis precipitation minus evaporation and sublimation (Gelaro et al., 2017). Using standard uncertainty propagation equations (Appendix A), we estimate an uncertainty of 7.2 m/yr for basal melt rates calculated between ICESat and REMA, and 11.5 m/yr for basal melt rates calculated

between REMA and ICESat-2. Most of the uncertainty comes from the error in the REMA DEM and, as noted in our above discussion of error in surface height change, we expect the highest uncertainty magnitudes at locations within the tile where REMA strips were feathered, and uncertainty magnitudes are lower than the values estimated here across most of the REMA tile.

3 Results

3.1 Twenty-year velocity and strain-rate records

We analysed the twenty-year velocity record at three scales: by calculating changes in small, fixed areas of interest, using Hovmöller diagrams to assess change along flowlines, and through annual composite maps that show patterns over the entire shelf. For our small areas of interest, we chose three square sites covering 9 km^2 in regions of the TEIS that behave in different ways (Fig. 1): site 1 crosses the 2011 grounding zone (Rignot et al., 2016), site 2 represents mid-shelf patterns, and site 3 is just upstream of the pinning point that constrains the ice shelf.

Figure 2 shows average values of ice-flow speed, direction, and longitudinal strain rate at the three sites. The change in ice speed over time yields the most consistent patterns in these different areas of the shelf, with all three showing a prominent peak in speed between 2005 and 2007. Following this peak, the grounding zone and mid-shelf sites display a small but steady increase in speed to the end of the record, while the pinning point site experiences more variability, with an increase in speed only in the last four years of the record.
Figure 2: Average values of speed, flow direction, and longitudinal strain rate at the three sites of interest (locations shown in Figure 1) for the 20-year velocity record.

Flow directions are presented in grid directions based on the WGS84 Antarctic Polar Stereographic projection (EPSG:3031) used in all figures in this study. Grid north is 0°, with values increasing clockwise. Following noise

305 early in the record, flow directions at the grounding zone site are extremely stable. The mid-shelf and pinning point sites show more variability, but both sites show an overall decrease in angle over time, with most of the decrease concentrated in the middle of the record, coincident with the large speed decrease seen in all three boxes. This means that flow directions at these two sites shifted from grid west (270°) or just south of grid west to a direction closer to grid south (counter-clockwise) over time.

310

Longitudinal strain rates show greater contrast between the shelf areas. The peak in 2004-2005 at the grounding zone site primarily reflects the retreat of the grounding line across this area. Because the MODIS-derived velocities (which are the primary data source early in the record) incorrectly show near-zero ice-flow speeds above the grounding line, the data yield artificially high longitudinal strain rates near the current grounding-line location.

315 While this does not reflect accurate strain rates, it does give an estimate of grounding-line location throughout the record.

Patterns of longitudinal strain rate show approximately opposite trends early in the record for the mid-shelf and pinning point sites. Between 2005 and 2007, coincident with the large speed increase noted in all boxes, the mid-

320 shelf site shows anomalously positive (extensional) longitudinal strain rates, while the pinning point site shows anomalously negative (compressional) strain rates. Following these anomalies, longitudinal strain rates in these boxes are approximately stable, but with a slight increasing trend. Longitudinal strain rates at the mid-shelf site switch from negative (compressional) to positive (extensional) in the last two years of the record, although the difference is very small.

325

To provide some spatial context for the observed patterns in these areas of interest while easily visualizing change throughout the full record, we utilized Hovmöller diagrams along two flowlines of interest (grey solid lines in Figure 1). These flowlines were generated based on Sentinel-1 data averaged between 2014 and 2020. Flowline A starts above the grounding line and flows through the main calving face of the TEIS towards grid north, while

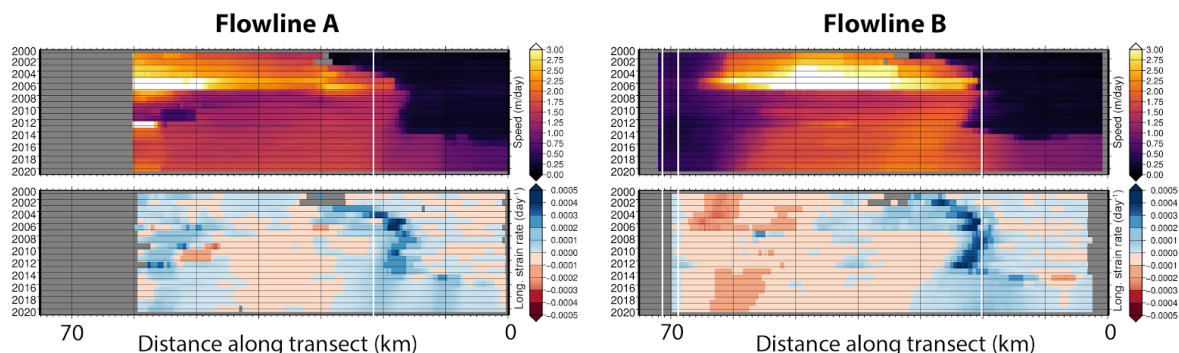
330 Flowline B starts above the grounding line and crosses the pinning point that confines the TEIS. The MEaSUREs 2011 grounding line (Rignot et al., 2016) is marked using vertical white lines on the Hovmöller diagrams in Figure 3. Note that the abrupt transition in velocity and strain rate near the grounding line during the first ~12 years of the record is an artefact of MODIS's inability to measure ice flow on grounded ice.


Figure 3: Hovmöller diagrams of speed and longitudinal strain rates from our long-term record along flowlines A and B (Figure 1). Vertical white lines represent the location of the Measures 2011 grounding line (Rignot et al., 2016).

335

The speed records in Figure 3 also show the increase in ice speed from the beginning of the record until ~2007 as noted in the sites of interest examined in Figure 2. This acceleration stretches from the grounding zone all the way to the calving front along Flowline A. The area of increased speed was confined to the region between the grounding zone and the pinning point on Flowline B, but it migrated towards the pinning point over time before
340 the floating ice shelf decelerated drastically in 2007. Both flowlines show fairly small but uniform increases in velocity following the slowdown in 2007, a trend that is consistent along the full length of the flowlines. Similar to the more drastic increase in velocity between 2000 and 2007, this acceleration during the second half of the record migrates towards the pinning point along Flowline B.

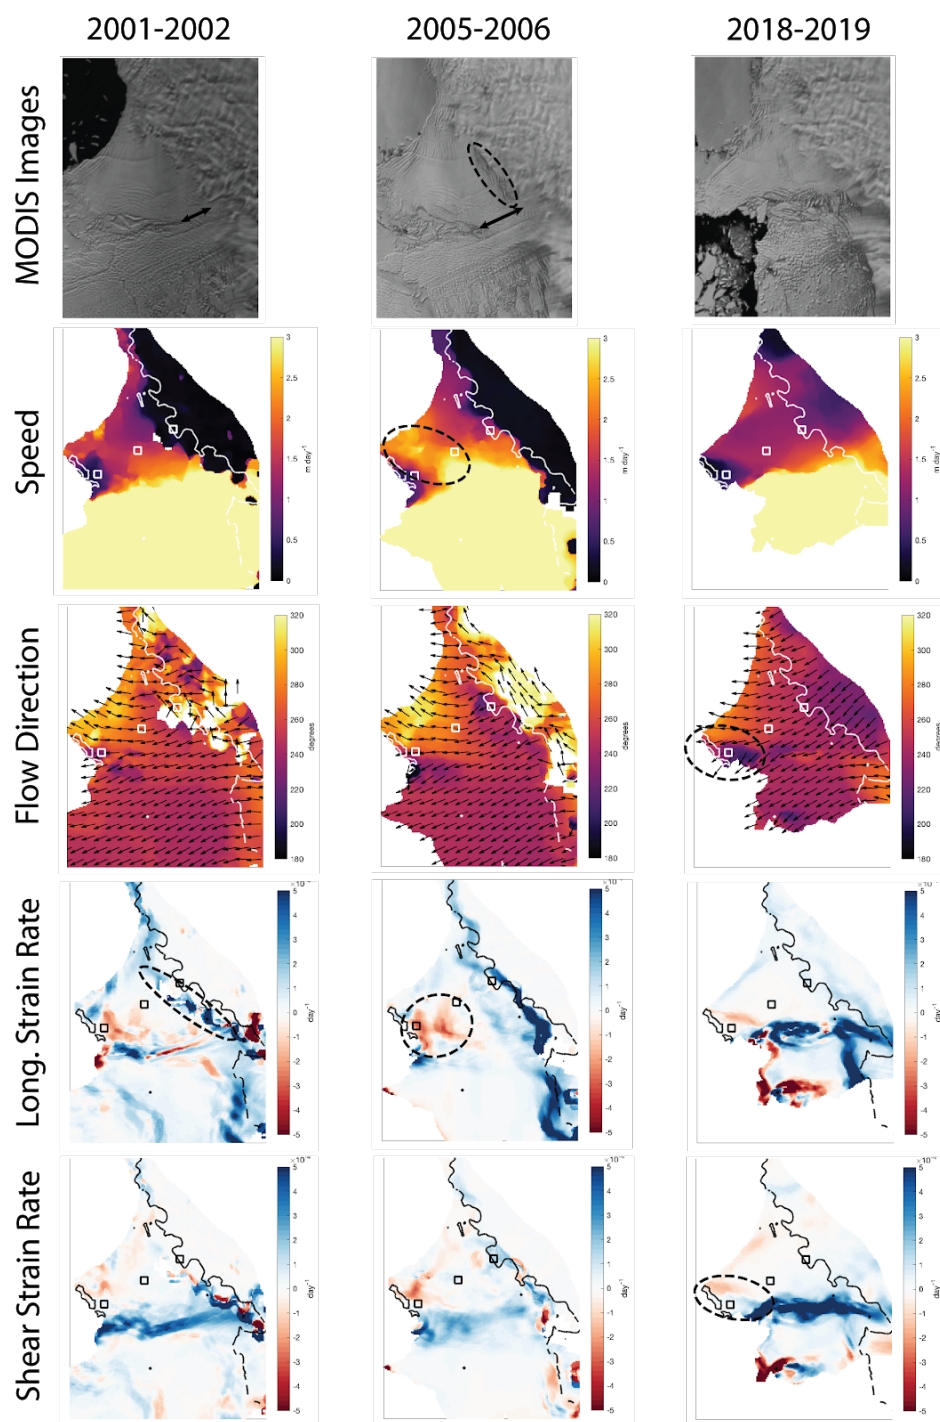
345 Longitudinal strain rates are represented as positive in extension (blue) and negative in compression (red). Extensional strain rates near the grounding zone are artificially high prior to 2013 in our mapping because MODIS data comprise most of the record. However, valid high longitudinal strain rates are indicated with the accurate grounded ice velocities determined from Landsat-8 pairs from 2013 onward, representing the flow acceleration as ice transitions from grounded to floating. Strain rates just downstream of the grounding zone were most extensive
350 during the 2000-2007 acceleration. Extensional strain rates are also found near the calving front along Flowline A throughout the record. Otherwise, longitudinal strain rates are primarily compressional on the TEIS, particularly in the shear zone in front of the seaward pinning point. During the latter part of the record, the zone of compressional strain rates in the pinning point shear zone narrow and migrate towards the pinning point.


Figure 4: Annual maps of TEIS variables. Black dashed ovals mark features discussed in the text.

355

Patterns of change are captured in yet more spatial detail by examining maps of each variable. Videos that show maps of speed, flow direction, and strain-rate components (longitudinal, transverse, and shear) alongside MODIS imagery representative of each season are available at the US Antarctic Program Data Center (Alley et al. 2021). We highlight key frames from these videos in Figure 4, including panels from early in the record (2001-2002),

360 during the large acceleration event (2005-2006), and late in the record (2018-2019). These spatial patterns, along with the change in our site examples and the Hovmöller diagrams, are discussed in Section 4.

3.2 5-year velocity and strain-rate record

In addition to the 20-year velocity record, we also produced a shorter-term, higher-temporal-resolution velocity

365 record from 2015-2020. For each variable, we produced four averages per year: spring (September, October, November), summer (December, January, February), fall (March, April, May) and winter (June, July, August). The winter averages are primarily derived from Sentinel-1 radar data, as visible-band images are not available during polar winter, while the summer images combine both Sentinel-1 and visible-band images from Landsat-8 and MODIS.

370

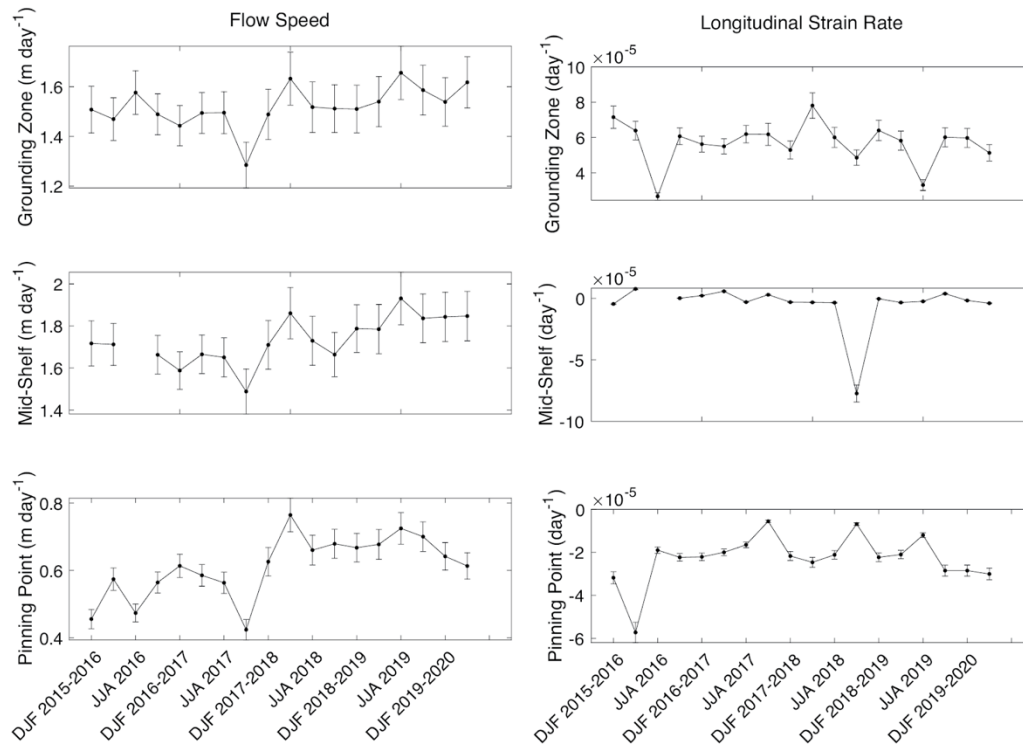
Figure 5 shows speed and longitudinal strain rates from the 5-year record averaged within the same study sites identified in Figure 1. The trends in Figure 5 are consistent with the long-term record trends shown in Figure 2, with increases in speed in all three boxes and more variability in the longitudinal strain rates. Notably, TEIS ice dynamics at these sites show no seasonal cycle.


Figure 5: Average values of speed, flow direction, and longitudinal strain rate at the three sites of interest (locations shown in Figure 1) for the 5-year velocity record.

375

Considerably more detail can be seen in Hovmöller diagrams in Figure 6, which display data from the same flowlines used in Figure 3. Figure 6 provides data from our combined 5-year record, as well as from a monthly record based only on Sentinel-1 data. This Sentinel-1 record is at both a higher spatial (100 m) and temporal (monthly) resolution than our combined 5-year record. In addition, strain rates are calculated on a shorter (200-m)
380 length scale, rather than on the longer, approximately viscous (5 km) length scale used in our combined record. The Sentinel-1 data are therefore more appropriate for looking at details of change over small spatial length scales, such as in the shear zone upstream of the TEIS pinning point, as they preserve sharp gradients in dynamic properties.

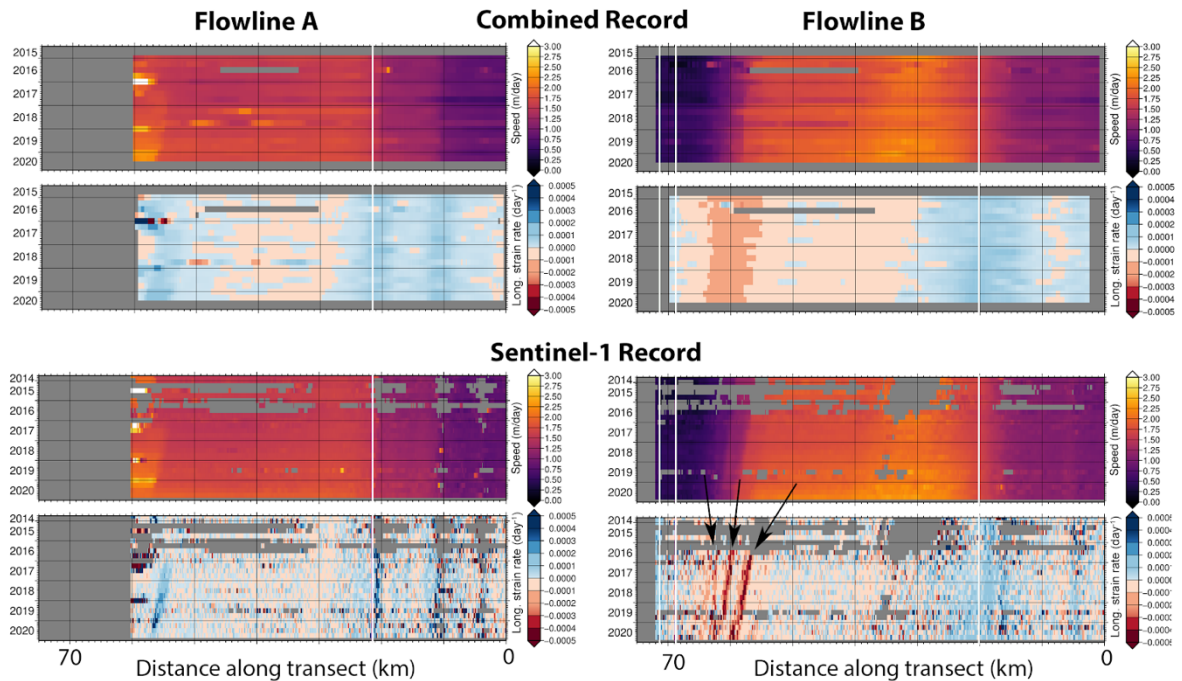
385 The migration of higher speeds towards the pinning point seen in the 20-year record is particularly evident in the Sentinel-1 record. Furthermore, the strongly negative longitudinal strain rates in this shear zone, which appear constant across it in the combined 5-year record, are seen to be concentrated in three distinct bands in the Sentinel-1 record, which we have marked with three black arrows. Two of these bands converge at the end of the record.


Figure 6: Hovmöller diagrams of speed and longitudinal strain rates from our combined 5-year record and from Sentinel-1 radar speckle tracking for flowlines A and B (Figure 1).

3.3. Surface elevation change and basal melt rates

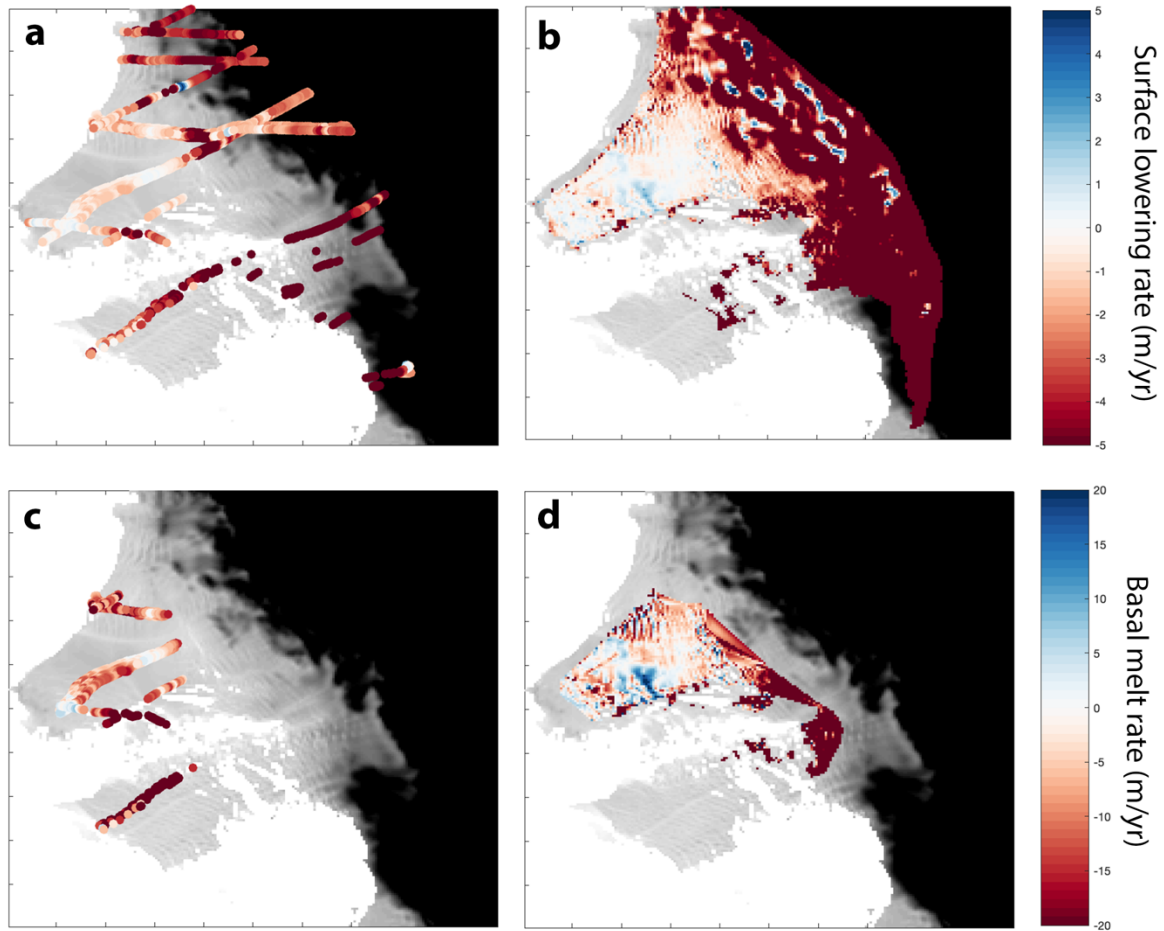
Figure 7 shows surface height change and basal melt rates calculated based on mass conservation on the TEIS. The left-hand column (panels a and c) shows change between ICESat (data points collected between 2003-2009) and REMA (DEM strips collected between 2013-2014), and the right-hand column (panels b and d) shows change between REMA and ICESat-2 (data points collected between 2018-2020). The first row (panels a and b) gives Lagrangian surface height change, while the second row (panels c and d) gives calculated basal melt rates for pixels on the freely floating ice shelf. All points are plotted with ICESat or ICESat-2 points migrated to their locations when the REMA data were collected. Surface height change and basal melt are calculated as annual averages over the time periods represented by each set of data points.


Figure 7: Lagrangian surface lowering and basal melt rates. The first row shows surface lowering between ICESat and REMA (panel a) and between REMA and ICESat-2 (panel b). The second row shows basal melt rates between ICESat and REMA (panel c) and between REMA and ICESat-2 (panel d). Surface height change and basal melt rates are interpolated to a standard 500 m grid in panels b and d.

400

The largest rates of surface-height change are found on grounded ice, both due to rapid dynamic thinning in these areas and because surface elevation changes on grounded ice are not hydrostatically compensated. Surface height change on the floating ice shelf is overall much slower. We note an area in the middle of the TEIS that shows 405 relatively rapid surface lowering in panel a, in the same location as relatively rapid surface height increase in panel b. These same areas display rapid melt in panel c and rapid freeze-on in panel d. This small, anomalous region

coincides with a seam between REMA DEM strips, with considerable feathering apparent in the mosaicking. The opposite signs of the signal in the two time periods suggest that the high rates of change here are due to REMA showing incorrectly low surface heights in this area, and not to a real surface height change. However, the consistency in trends in the rest of the data between the two time periods give us confidence in the calculated trends over the majority of the TEIS.

Basal melt rates generally reflect the same patterns as surface-height changes, suggesting that basal melt is the primary cause of surface-height changes on the floating TEIS. Variability in basal melt is particularly high in the shear zone upstream of the pinning point and in the heavily rifted area downstream of the grounding line in the grid-north quadrant. This variability may reflect inaccurate Lagrangian migration of points; areas with extensive rifting have widely varying ice thicknesses, which would clearly show inaccuracies in tracking of ice parcels. However, we also note that melt rates are typically much higher on near-vertical faces, and these vertical faces migrate laterally as a result, increasing basal melt rate variability in areas with highly variable ice thicknesses, (e.g. Dutrieux et al., 2014).

4. Discussion

4.1 Influence of the Thwaites Western Ice Tongue

The clearest dynamic control on the TEIS during the first half of the 20-year velocity record presented here is the Thwaites Western Ice Tongue (TWIT). The TWIT is the floating extension of the main trunk of Thwaites Glacier, and has speeds that are typically two to four times higher than those found on the TEIS. A prominent shear margin separates the TEIS and TWIT, which has had highly variable coherence throughout the record. Early in the record, a relatively short but strong shear margin was present near the grounding line, as indicated with a black arrow in the 2002 MODIS image in Figure 4. The extent of this coherent, strong shear margin increased over the next several years, achieving its greatest length around 2006, as shown in the 2006 MODIS image in Figure 4.

We deduce that this shear margin was strong based on both the lack of large fractures at this time and on the acceleration of the TEIS, supporting the interpretations of other authors (Miles et al., 2020; Mouginot et al., 2014). As shown in Figures 2-4, the TEIS experienced significant acceleration early in the record, peaking around 2005-2007. The 2001-2002 map of speed in Figure 4 shows that the highest speeds on TEIS at this time were found near the shear margin. We interpret this to be a result of large shearing stresses and higher TWIT speeds that dragged this part of TEIS forwards. This effect became most pronounced during the 2005-2006 season, when the zone of high speeds spread through the middle of the ice shelf, as marked with a dotted oval in the 2005-2006 speed image in Figure 4. By 2007, large rifts developed across the shear margin (see MODIS images in Supplementary Videos

440   1-5), and by the 2008-2009 season a full separation between the TEIS and TWIT had developed in the shear margin. As it was no longer being dragged forwards by the TWIT, the TEIS decelerated significantly at this point. The TWIT nearly completely detached and disintegrated in the following years.

    Acceleration on the TEIS while the shear margin was strong also added a new set of surface features to the TEIS.

445   A swarm of crevasses opened along the grounding line during this increase in velocity, shown within the dotted oval in the 2006 MODIS image in Figure 4, with more forming at the grounding line over the next few years. These crevasses are also visible in the Landsat time series of the TEIS shown in Figure 8, starting in the 2005 image where we have marked their formation area with a dotted oval. The crevasse swarm can be seen to advect into the main floating ice shelf throughout the rest of the images in Figure 8; we have indicated this swarm with

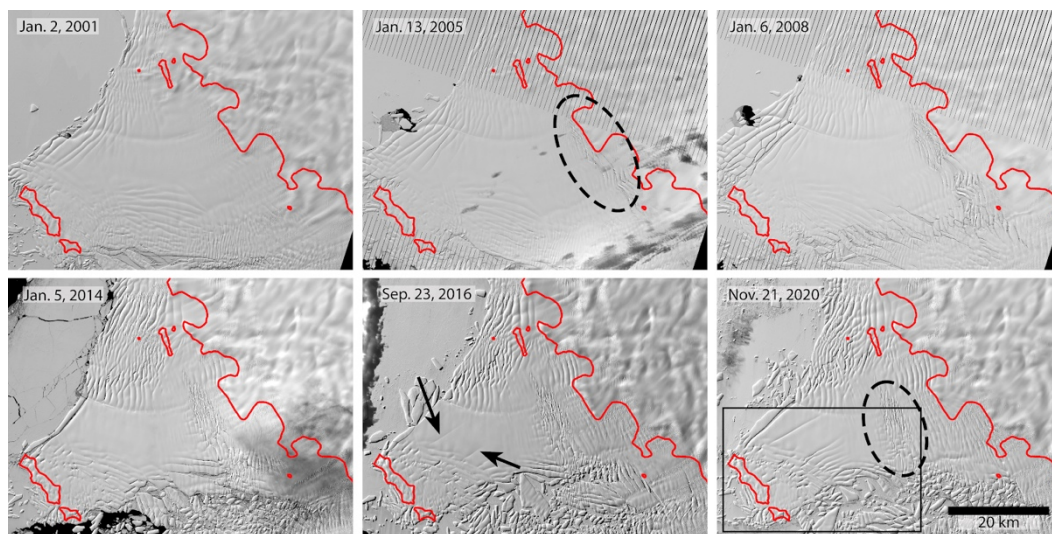
450   another dotted oval in the 2020 image.


Figure 8: Landsat-7 and Landsat-8 time series of the TEIS from 2001-2020. Arrows and ovals are discussed in the text. The rectangle in the 2020 images represents the subset area shown in Figure 9.

4.2 The TEIS pinning point and pinning point shear zone

    Aside from the influence of the TWIT, the pinning point that confines the TEIS has had the greatest impact on the

455   shelf's spatial patterns of ice-flow speed, direction, and strain rates. This pinning point transmits backstress upstream, as evidenced by the zone of slow velocities consistently found just upstream of the pinning point. That backstress is particularly evident in the 2005-2006 longitudinal strain-rate image in Figure 4, which shows a large zone of negative (compressional) longitudinal strain rates upstream of the pinning point, which is marked with a

dotted oval. As the TWIT dragged the TEIS forward at this time, the pinning point provided widespread resistance to this dragging.

Although the backstress transmitted from the pinning point is an overall stabilizing force for the TEIS, the clearest signs of destabilization are now concentrated in this area. As shown in Figure 2, average flow directions on the shelf have rotated toward grid-south (counter-clockwise) during the latter part of the 20-year record. When the TWIT was intact, the presence of the coherent ice tongue largely prevented the ice of the TEIS from outflowing in that direction. With the TWIT removed, TEIS ice flow is now showing strong patterns of divergence around the pinning point, as seen in the 2018-2019 flow direction image in Figure 4 (marked with a dashed oval). This directional divide is also clearly identifiable in the shear-strain values in the 2018-2019 panel in Figure 4 (marked with a dashed oval), which shows a zone of left-lateral shearing that has developed to the grid south of the pinning point and right-lateral shearing to grid north.

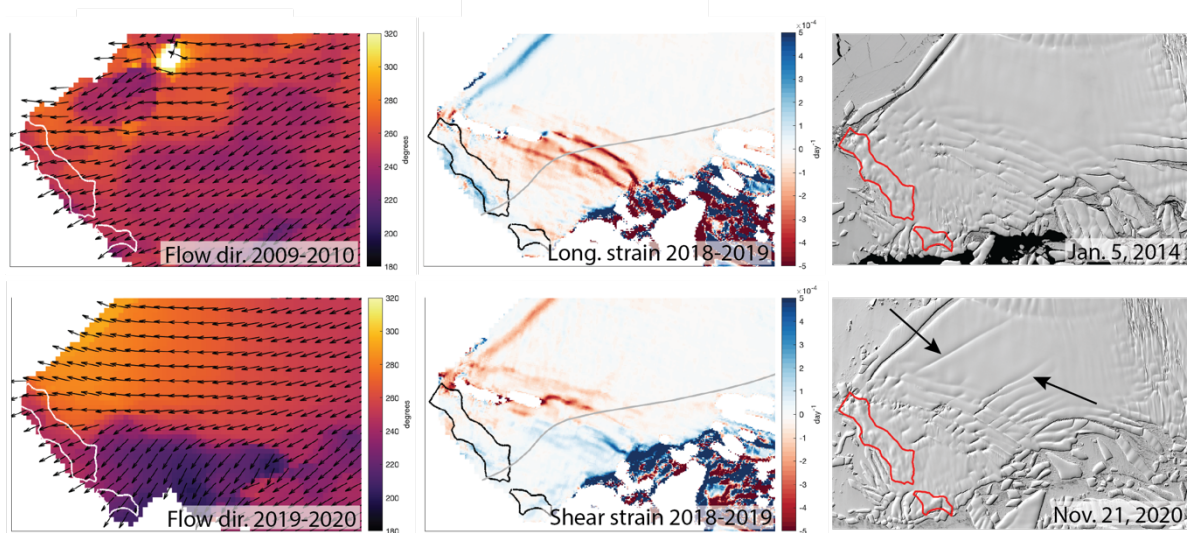
Figure 9 provides a close-up of the TEIS pinning point shear zone. The first column shows the 2009-2010 flow direction field, before the flow divergence was distinct, and the 2019-2020 flow direction field, which shows that the pattern has developed into distinct regions of contrasting flow direction with a boundary that closely coincides with the pinning point shear zone. The second column shows longitudinal and shear strain rates derived from Sentinel-1 data during summer 2018-2019. The top panel in this column shows the distinct bands of concentrated longitudinal strain rates noted in the Hovmöller diagram in Figure 6. These bands of concentrated strain likely stretch farther towards the main calving front to grid northwest, but that region is subject to consistent data gaps during the record. Because the strain appears to be concentrating along rifts, shown in the Landsat-8 images in the third column of Figure 9, which extend across most of the shelf in the shear zone, it is reasonable to assume that these concentrated bands of strain also extend across most of the shelf. The 2018-2019 Sentinel-1 shear strain rates in Figure 9 show strain concentration in the same bands but reveal a contrasting sense of shear consistent with the split flow directions.


Figure 9: Detail of the shear zone upstream of the TEIS pinning point showing the evolution of key features over time. First column: Two-year averages of flow direction, showing a split in flow direction around the pinning point that had not clearly developed by the 2009-2010 image, but had become very distinct by 2019-2020 image. Second column: Longitudinal and shear strain rates derived from Sentinel-1 imagery showing distinct bands of high strain rates in the pinning point shear zone. Gray line is Flowline B (Figure 1). Third column: Landsat-8 images showing the development of large rifts and smaller fractures nucleating in the pinning point shear zone. Red outline in all panels is the grounded pinning point from the 2011 MEaSURES dataset (Rignot et al., 2016). Subset region is indicated in Figure 8.

485

The Hovmöller diagrams in Figure 6 show that the bands of concentrated strain rates migrate towards the pinning point over time, as does the region of higher speeds upstream of the pinning point shear zone. This migration is occurring at approximately the same speed as ice flow, which may indicate that these dynamic changes are advecting with the ice as the TEIS continues to adjust to the loss of the TWIT. However, the migration of
490 concentrated strain and higher velocities towards the pinning point may alternatively or additionally indicate that the TEIS pinning point is ungrounding, removing backstress that has prevented this change in the past. The new flow divergence around the pinning point suggests that thinner ice is being delivered to the pinning point, which could promote ungrounding. Analysis of pinning point evolution is ongoing and will be presented in a separate paper.

495

Simultaneous with the development of divergence in ice flow around the pinning point, new, relatively small rifts have begun to form within the shear zone, and large, laterally extensive rifts have nucleated from the shear zone

and extended into the middle of the shelf. These large rifts first appear in 2016 and are marked in the 2016 Landsat-8 image in Figure 8, as well as in the 2020 Landsat-8 image in Figure 9. As these rifts have formed within regions of high shear strain in the pinning point shear zone, they are likely caused at least in part by the new pattern of flow divergence around the pinning point.

In addition, Figure 7 shows sustained, concentrated areas of relatively high rates of surface lowering and basal melt in the pinning point shear zone. Surface lowering and basal melt rates in this region are highly spatially variable, which may be related to variability in ice thickness and basal slope due to the presence of rifts and basal crevasses. Large differences in ice thickness may exaggerate errors in the Lagrangian migration of points, resulting in false variability in surface height change and basal melt. However, there is also reason to believe that basal melt rates should be highly variable in fractured basal ice, as cold meltwater insulates relatively horizontal ice from melt while melt rates can be much higher on ice faces that are closer to vertical (e.g. Dutrieux et al., 2014). These values may therefore reflect localized high rates of real basal melt and thinning in this shear zone, which may also have contributed to the formation of large rifts within the shear zone.

4.3 TEIS and ocean forcing

Figure 7 shows that patterns of surface elevation change and patterns of basal melt on the floating ice shelf are very similar. Basal melt was calculated from mass conservation, taking into account surface mass balance and ice thickness divergence to explain the observed changes in surface height. Similarity between the patterns of basal melt and surface lowering suggests that surface mass balance and ice flux divergence contribute little to surface-height changes, and that the vertical TEIS changes are driven by ocean forcing.

This is not an especially surprising result, as many studies (e.g. Pritchard et al., 2012) have shown that dynamic changes in the Amundsen Sea are driven by strong basal melt forcing by warm Circumpolar Deep Water (CDW). However, although CDW presence leads to an overall increase in ice shelf basal melt and thinning, spatial and temporal details may be much more complex. Seroussi et al. (2017) ran a 50-year simulation of basal melt beneath the TEIS, showing that melt rates initially decrease as the ice shelf base thins out of the reach of CDW, before melt rates increase with continued climate forcing. This separation from CDW on the relatively flat basal topography in the mid-TEIS may be responsible for the relatively low basal melt and thinning rates in this area. Although the ice draft is not significantly different than the middle of the shelf, the higher basal melt and thinning rates seen near the grounding line and pinning point shear zone may be due to the presence of steep basal topography prone to faster melt.

Another potential control on thinning in these areas may be directly related to patterns of ocean currents beneath the TEIS. Wåhlin et al. (2021) used CTD casts and an autonomous underwater vehicle to measure water properties near and beneath the TEIS during a 2019 cruise. Identified pathways of warm water inflow include previously underestimated branches from the east, roughly following bathymetric troughs beneath the main calving front of the TEIS, and significant heat inflow through troughs from the north along the TWIT/TEIS shear margin. These observational data add considerable detail and new information to results produced by Nakayama et al. (2019), who used a high-resolution ocean model to show that increased basal melt rates on the TEIS coincide with faster sub-ice-shelf currents. Modelled (Nakayama et al. 2019) and observed (Wåhlin et al. 2021) warm inflows coincide roughly with the areas where we observe relatively large rates of thinning and bottom melting (Figure 7), including near the grounding line to the east and in the shear zone upstream of the TEIS pinning point.

These results suggest that direct ocean forcing is a possible explanation for the earlier unpinning and disintegration of the TWIT. Modelled currents and melt rates were found to be faster beneath the TWIT than the TEIS (Nakayama et al., 2019), and the heat transport in one of the deep troughs leading under the TWIT/TEIS shear margin was very high (Wåhlin et al. 2021). Furthermore, Wåhlin et al. (2021) suggest that the ocean heat transport observed to be currently influencing the TEIS pinning point is unsustainably high and may lead to unpinning and destabilization in the style of the TWIT. Assuming that the TEIS pinning point experienced stable melt rates in previous decades, the observed high heat fluxes may be due to an externally forced change in ocean circulation, and/or could relate to a positive feedback where a reduction in ice-shelf draft due to basal melt allows increased inflow of warm water. So, while the observed TEIS ice flow changes may be responding to ice-dynamic controls from the TWIT and upstream ice, they may also be directly due to ocean circulation changes that have increased heat fluxes and basal melt, thinning and weakening the ice shelf near the crucial TEIS pinning point.

5. Conclusions and future outlook for the TEIS

The past 20 years of change on the TEIS were dominated by dynamic interaction with the neighbouring TWIT. Early in the record (~2000-2006), the TEIS experienced large lateral stresses from the more rapidly flowing TWIT, causing the TEIS to accelerate. This was followed by rapid TEIS deceleration as the TWIT/TEIS shear margin weakened and the TWIT decoupled and disintegrated around 2007. The TEIS then developed new, independent flow patterns, including an overall ice velocity increase. The pinning point responsible for maintaining TEIS stability has now become an epicentre of destabilization. During the last several years of the record, ice flow has strongly diverged around the pinning point and strain rates have concentrated in narrow bands in the shear zone upstream. Simultaneously, significant fracturing has nucleated within the region of high strain rates and several rifts have penetrated much of the TEIS's central region.

565   Sparse measurements of surface lowering rates are available between ~2003 and 2014 from ICESat and REMA, with much more detail available between ~2014 and 2020 from REMA and ICESat-2. These data show generally low thinning and basal melt rates in the central TEIS, with much more variable and overall higher basal melt rates near the grounding line and in the shear zone upstream of the pinning point. The presence of relatively high thinning rates is particularly important in the pinning point shear zone, where basal melt may be partially

570   responsible for weakening that has led to new rift formation.

Both the vertical and horizontal changes observed on the TEIS over the last 20 years indicate progressive weakening and destabilization of the floating ice shelf. There is no indication that these trends will reverse in the future. Increased forcing by CDW is likely to continue (e.g. Holland et al., 2019), and upstream acceleration and

575   thinning of Thwaites Glacier means that ice advected onto the shelf may be more damaged (e.g. MacGregor et al., 2012). The patterns of dynamic instability that we have observed indicate that weakening will enhance over time (see also Joughin et al., 2014; Rignot et al., 2014). Based on this analysis, the future of the TEIS looks much like what we have already seen on the TWIT: a total or near-total loss of the floating ice shelf, removing the buttressing connection with the pinning point and resulting in acceleration of grounded ice. We suggest that final disintegration

580   of the TEIS will occur in one of three possible ways:

1. The surface crevasse swarm that nucleated at the grounding zone around 2005 will continue to advect, reaching the central region of the shelf that is now penetrated by large rifts. These damaged areas will join in 10-20 years and may destabilize the TEIS throughout its central region. The impact of this event

585   will depend on whether new, large rifts continue to nucleate from the pinning point shear zone, and the evolution of the crevasse swarm (further extension, or healing) as it continues to advect. The condition of the crevasse swarm will depend largely on mid-shelf longitudinal strain rates, which are primarily compressional, but are trending towards neutral or extensional.

2. The ice shelf may decouple from the pinning point due to large-scale failure in the pinning point shear

590   zone. Based on the rapid development of rifting within the shear zone in the last ~5 years, this could plausibly occur on a timescale of years to decades. The pace of this failure is likely to be set by the basal melt rate and the continued concentration of stress along large rifts extending across the pinning point shear zone. We note, however, that break-up of other ice shelves has been highly non-linear and that a sufficiently thin and weak shelf can break up very rapidly.

595   3. Continued ocean-forced thinning of the ice shelf and advection of thinner ice onto the pinning point will result in partial or complete unpinning of the ice shelf and loss of integrity. The extensive flow changes

and migration of high velocities towards the pinning point over the last decade suggest that this process is underway and could destabilize the shelf in one to two decades.

600 **Acknowledgments**

This work is from the TARSAN project, a component of the International Thwaites Glacier Collaboration (ITGC). Support from National Science Foundation (NSF: Grant 1929991) and Natural Environment Research Council (NERC: Grant NE/S006419/1). Logistics provided by NSF-U.S. Antarctic Program and NERC-British Antarctic Survey. Sentinel-1 data were provided by the Copernicus Program of the European Commission. We thank 605 Fernando Paolo, Luc Girod, and Richard Alley for advice on data preparation methods, and Anna Wåhlin for her comments on this manuscript.

Author contributions

K. Alley led data analysis and writing. C.T. Wild produced alpha maps and assisted in analysis of altimetry and 610 REMA data. A. Luckman analysed all Sentinel-1 data and provided figures for the manuscript. C.T Wild, T.A. Scambos, M. Truffer, E.C. Pettit, and A. Muto assisted in data analysis and manuscript planning. B. Wallin and M. Klinger provided data and expertise in MODIS imagery and PyCorr processing. T. Sutterley and C. Hulen assisted in processing of ICESat-2 data. S. F. Child assisted in analysis of the REMA DEM in relation to ICESat and ICESat-2 data. J.T.M. Lenaerts, M. Maclennan, E. Keenan, and D. Dunmire provided data processing for firn-615 air thickness and surface mass balance used in basal melt rate calculations. All authors participated in the writing and revision of the manuscript.

825

Appendix A:

830 To estimate the error in our calculations of basal melt rates, we use standard equations of error propagation. First, we find the error associated with ice thickness. We rearrange equation 2 from the main text to solve for H, and then propagate the error:

$$\frac{z_s - \left(\frac{\rho_i}{\rho_w}\right) h_a}{\left(1 - \frac{\rho_i}{\rho_w}\right)} = H \qquad (A1)$$

835

Error in first (Z_s) term on the top of the fraction is $\sigma_{1REMA} = 6\ m$ for the REMA mosaic and $\sigma_{1ICES} = 0.2\ m$ for ICESat and ICESat-2. Error in h_a is $\sigma_{h_a} = 1\ m$, which takes into account the time-variability in firn-air content as described in the text. The error in the second term can then be expressed:

840
$$\sigma_2 = \left(\frac{\rho_i}{\rho_w}\right) \sigma_{h_a} = 0.89\ m \qquad (A2)$$

We use error propagation for addition and subtraction for the top of the fraction in equation A1:

$$\sigma_{H\_top} = \sqrt{\sigma_1^2 + \sigma_2^2} \qquad (A3)$$

845 $\sigma_{H\_top} = 6.1\ m$ for REMA and 0.91 m for ICESat/ICESat-2. Then we divide by the constant value on the bottom in equation A1 to get the total error in H for REMA and for ICESat/ICESat-2: $\sigma_{H\_REMA} = 57\ m$ and $\sigma_{H\_ICES} = 8.6\ m$.

Now we find the error in basal melt rate by propagating the error in ice thickness and other terms through Equation

850 3 from the main text (repeated here for reference):

$$\frac{DH}{Dt} + H(\dot{\epsilon}_{trans} + \dot{\epsilon}_{lon}) = \dot{m}_s + \dot{m}_b \qquad (3)$$

To find the error in the first term, we start with error propagation for addition and subtraction, then divide by Dt:

855
$$\sigma_{DHDT} = \frac{\sqrt{\sigma_{HREMA}^2 + \sigma_{HICES}^2}}{Dt} \qquad (A4)$$

This yields an error estimate of $\sigma_{DHDT} = 11.5$ m/yr for REMA to ICESat-2 and $\sigma_{DHDT} = 7.2$ m/yr for ICESat to REMA. Error in second term is treated as a constant multiplied by added uncorrelated errors:

860

$$\sigma_2 = 250 * \sqrt{(4 * 10^{-4})^2 + (4 * 10^{-4})^2} = 0.14 \ m/yr \quad\quad (A5)$$

Error in $\dot{m}_s$ is estimated to be 0.1 m of ice equivalent per year. Altogether, therefore, the error in basal melt rate is calculated as:

865

$$\sigma_{\dot{m}_b} = \sqrt{\sigma_{DHDT}^2 + \sigma_2^2 + \sigma_{SMB}^2} \quad\quad (A6)$$

This yields an error estimate of $\sigma_{\dot{m}_b} = 11.5$ m/yr for REMA to ICESat-2 and $\sigma_{\dot{m}_b} = 7.2$ m/yr for ICESat to REMA.
