Abstract. Accurate knowledge of snow depth distributions in forested regions is crucial for applications in hydrology and ecology. Understanding and assessing the effect of vegetation and topographic conditions on ~~the~~ snow depth variability is useful for ~~the~~ accurate prediction of snow depths. In this study, the spatial distribution of snow depth in two agro-forested sites and one coniferous site in eastern Canada was analyzed for topographic and vegetation effects on snow accumulation. Spatially distributed snow depths were derived by Unmanned Aerial Vehicle Light Detection and Ranging (UAV-lidar) surveys conducted in 2019 and 2020. Distinct patterns of snow accumulation and erosion in open areas (fields) versus adjacent forested areas were observed in lidar-derived snow depth maps at all sites. Omnidirectional semi-variogram analysis of snow depths showed the existence of a scale break distance of less than 10 m in the forested area at all three sites, whereas open areas showed ~~scale invariance or~~ comparatively large scale break distances (i.e., ~~18~~ 11–14 m). The effect of vegetation and topographic variables on the spatial variability of snow depths at each site was investigated with random forest models. Results show that including wind-related forest edge proximity effects ~~improved the model accuracy by more than 50 %~~ in agro-forested sites~~,~~ ~~whereas~~ and incorporating canopy characteristics ~~improved the model accuracy by more than 60 %~~ in the coniferous site increased the model prediction accuracy by more than 90 %. Hence the underlying topography and the wind-redistribution of snow along forest edges govern the snow depth variability at agro-forested sites, while forest structure variability dominates snow depth variability in the coniferous environment. These results highlight the importance of including and better representing these processes in ~~process~~physically-based models for accurate estimates of snowpack dynamics. This study also demonstrates the usefulness of UAV-lidar to resolve and understand high-resolution snow depth heterogeneity in agro-forested environments and boreal forests.

1 Introduction ~~/ problematic~~

Knowledge of spring snowpack conditions is essential to accurately estimate water availability and flood peaks following the onset of melt (Hopkinson et al., 2004). Many studies showed that addressing the spatial distribution of snow depth prior to

melting is more important than spatial differences in melt behavior when estimating melt dynamics of the snowpack (e.g., Schirmer and Lehning, 2011; Egli et al., 2012). Evaluating snowpack conditions in forested regions is particularly crucial as the forest cover significantly modifies snow accumulation and ablation processes due to canopy interception and changes energy balance processes within the canopy. These changes produce a marked effect on ~~the~~ downstream hydrographs (Roth and Nolin, 2017). In addition, forests can also influence ~~the~~ differential snow accumulation by preferential deposition of wind-blown snow along the forest edges (Essery et al., 2009; Currier and Lundquist, 2018).

Spatial variability of the snow cover is mainly controlled by topography~~, and~~ vegetation type, and vegetation density (Golding and Swanson, 1986; Jost et al., 2007; Varhola et al., 2010a; Koutantou et al., 2022). With the advent of remote sensing techniques, airborne (piloted and unpiloted) laser (lidar: light detection and ranging) scanning techniques have been extensively used to monitor snowpacks due to their strong penetration ability through the canopy to detect underlying snow cover/ground (Hopkinson et al., 2004; Morsdorf et al., 2006; Hopkinson et al., 2010; Deems et al., 2013; Harpold et al., 2014; Zheng et al., 2016; Currier and Lundquist, 2018; Zheng et al., 2018; Mazzotti et al., 2019; Harder et al., 2020; Jacobs et al., 2021). Lidar scanning also typically allows capturing high-resolution micro ~~(<100 m) (e.g., Deems et al., 2013; Harder et al., 2020; Koutantou et al., 2021; Dharmadasa et al., 2022)~~and mesoscale ~~(100 m–10 km)~~ variability and allows producing high resolution (<10 m) snow depth/cover maps (e.g., Deems et al., 2013; Harder et al., 2020; Koutantou et al., 2021; Dharmadasa et al., 2022).

Field Code Changed

Field Code Changed

Snow spatial variability can occur on more than one scale due to different processes acting over multiple scales (Deems et al., 2006; Clark et al., 2011). Several studies emphasized a multiscale behavior of snow depths with two distinct regions (scales) separated by a scale break at a location varying from meters to tens of meters, with a more strongly spatially correlated snow depth structure before the scale break (Deems et al., 2006; Fassnacht and Deems, 2006; Trujillo et al., 2007; Deems et al., 2008; Trujillo et al., 2009; Mott et al., 2011; Schirmer and Lehning, 2011; Helfricht et al., 2014; Clemenzi et al., 2018; Mendoza et al., 2020a; Mendoza et al., 2020b). In turn, this suggests the existence of different combinations of processes controlling the snow accumulation, and distribution over these two distinct scales. For instance, these studies emphasized that canopy interception causes a short scale break distance in forested areas (9–12 m) ~~is reflected by canopy interception~~ where the effect of wind redistribution is minimal (Deems et al., 2006; Trujillo et al., 2007). Comparatively ~~a~~ longer distances (15–65 m) were reported in tundra regions ~~is~~ and ~~reflected~~ explained by the interaction of wind, vegetation, and terrain roughness (Trujillo et al., 2009), while a shorter (6 m) and longer (20 m) distance in non-vegetated areas are explained by the interaction of the wind with terrain roughness in sheltered and exposed mountain slopes, respectively (Mott et al., 2011; Schirmer and Lehning, 2011). The ~~knowledge~~ estimation of this scale break location is important ~~to choose~~when choosing the horizontal resolution required for remotely sensed or in situ data collection efforts, and model scales in order to represent the snowpack variability at different scales.

In addition to the scaling properties of snow distribution, the relationship~~s~~ between snow depth, topography, and forest structure ~~are~~ is also an important aspect in understanding/assessing small-scale snow heterogeneity in forested environments. The need to quantify these complex relationships has inspired the development of ~~modeling approaches like~~ numerous

empirical models (e.g., Anderton et al., 2004; Winkler et al., 2005; Grünewald et al., 2013) and process-based models (e.g., Hedstrom and Pomeroy, 1998; Liston and Elder, 2006; Mazzotti et al., 2020a; Mazzotti et al., 2020b). While process-based models are applicable to a wide range of conditions, they do require an extensive amount of input data. Contrarily, empirical models are useful in establishing a general relationship between the variables and provide a first-order estimate of their effects on snow processes. However, they do not explicitly account for governing processes, and thus may not make accurate predictions under specific conditions (Varhola et al., 2010a). Nevertheless, the use and effectiveness of empirical models like multiple linear regressions (MLR) (Jost et al., 2007; Lehning et al., 2011; Grünewald et al., 2013; Revuelto et al., 2014; Zheng et al., 2016; Zheng et al., 2018) and binary regression trees (BRT) (Elder et al., 1995; Elder et al., 1998; Winstral et al., 2002; Anderton et al., 2004; Molotch et al., 2005; Baños et al., 2011; Revuelto et al., 2014) to relate snow depth/SWE patterns with terrain and land cover predictors is well documented. Compared to linear methods, tree-based methods have the ability to describe more complex and nonlinear relationships between snow depth and ~~the independent~~landscape variables (Erxleben et al., 2002; Veatch et al., 2009; Bair et al., 2018). In recent years, the random forest (RF) model, an ensemble machine learning algorithm that combines several randomized decision trees and aggregates their predictions, started gaining popularity in water science and hydrological applications (Tyralis et al., 2019). The use of the ensemble bagging approach in RF models reduces overfitting, which is a well-known issue with traditional decision trees, and provides more accurate and unbiased error estimates (Breiman, 2001). As yet, there is only a handful of studies that used RF models to estimate snow depths/SWE (Bair et al., 2018; Yang et al., 2020) other than those that used RF algorithm to ~~express~~ quantify~~ing~~ the relative importance of predictor variables (Zheng et al., 2016) or to predict spatially distributed lidar vertical errors (Tinkham et al., 2014).

To our knowledge, to date, there are only a few previous studies that estimated snow depths by unpiloted aerial vehicle (UAV) based lidar (Harder et al., 2020; Cho et al., 2021; Jacobs et al., 2021; Koutantou et al., 2021; Dharmadasa et al., 2022) ~~(Harder et al., 2020; Cho et al., 2021; Jacobs et al., 2021; Koutantou et al., 2021; Dharmadasa et al., 2022; Koutantou et al., 2022; Proulx et al., 2022)~~. None of them explicitly examined how terrain and vegetation characteristics influence ~~the~~ snow heterogeneity in different landscapes. From previous studies, Koutantou et al. (2022) successfully used UAV-lidar data on two opposing slopes with a heterogeneous forest cover at a high spatio-temporal scale to show the effect of canopy structure and solar radiation on snow dynamics, excluding the effect of microtopography. The main objective of this paper is to study the small-scale spatial variability of snow depth by UAV-lidar and investigate the terrain (including the effect of microtopography) and vegetation controls on this snow depth heterogeneity in an agro-forested and a boreal landscape. The study sites are based in southern Québec, Canada, where forests intertwined with mosaics of open agricultural fields in low-lying lands (agro-forested landscapes) play a significant role in altering the spatial distribution of the snow cover (Aygün et al., 2020). Much uncertainty still exists about the micro and meso scale spatial variability of snow cover and associated hydrological processes in these landscapes, partly due to lack of detailed and simultaneous micrometeorological and snowpack observations (Brown, 2010; Sena et al., 2017; Valence et al., 2022). To our knowledge, there has been no application of UAV laser scanning to investigate the small-scale snow cover heterogeneity in this type of landscape. ~~As well, this paper provides some of the earliest results of snow depth mapping by UAV-lidar.~~ This study will specifically explore: (1) how the snow accumulation and its

scaling characteristics vary between and within forested and open environments, and (2) the relationship between snow depth, topography, and forest structure in different sites. Motivated by previous works (Currier and Lundquist, 2018; Mazzotti et al., 2019), we ~~included~~specifically investigate how the forest edges modulates the accumulation patterns in agro-forested environments. Given the relatively flat topography in these environments, we postulate that preferential accumulation along forest edges may represent a significant factor of spatial variability in snow depth. ~~forest edge effects in our study to investigate if they exert greater control on snow depth variability in these environments~~

2 Data and methods

2.1 Study sites

Small-scale snow depth heterogeneity was investigated at three selected sites that represent the typical landscape in southern Québec (Fig. 1). Of the three sites, Sainte-Marthe and Saint-Maurice are agro-forested sites located in the St. Lawrence River lowlands. Irrigation canals and streams flowing through the open agricultural areas are very common in these agro-forested landscapes. The main crop type in the agricultural areas is soya. The forested area in Sainte-Marthe consists of a dense deciduous forest with sugar maple (*Acer saccharum*), red maple (*Acer rubrum*), and a small conifer plantation to the southwest. Saint-Maurice has a high to moderate dense mixed forest with poplar (*Populus x canadensis*), red maple, white pine (*Pinus strobus*), and balsam fir (*Abies balsamea*) being the dominant tree species. Forêt Montmorency (hereafter Montmorency) is a dense boreal forest with balsam fir, black spruce (*Picea mariana*), and white spruce (*Picea glauca*) tree species farther north on the Canadian Shield. Forest gaps associated with clear-cutting and regeneration practices are common in this area. Adjacent to the forest is an open area hosting the NEIGE-FM snow research station, which hosts a variety of precipitation gauges and snowpack measuring sensors, and is part of the World Meteorological Organization's (WMO) station network (Royer et al., 2021). Table 1 summarizes the physiographic and climatic conditions at each site. Land use information presented in Fig.1 was obtained from the Québec Ministry of Forests, Wildlife, and Parks (MFFP). For the interpretation purpose, open agricultural areas in Sainte-Marthe and Saint-Maurice and the small open area in Montmorency (NEIGE-FM site) are referred to as "field" herein.

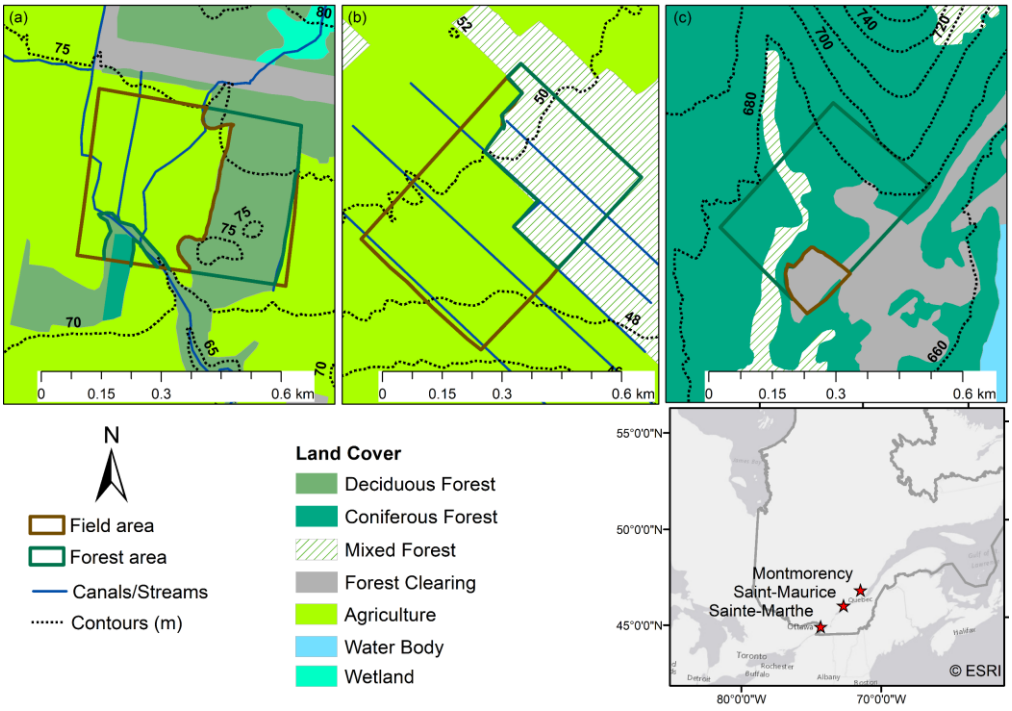

Figure 1. Overview of the study sites with lidar survey extents. Field and forest areas within each lidar extent are ~~demarcated~~delineated with brown and green colors, respectively. **(a)** Sainte-Marthe, **(b)** Saint-Maurice and **(c)** Montmorency. Contour intervals intentionally differ between sites for better readability. (Adapted from Dharmadasa et al. (2022) ~~the data from MFFP~~)

Table 1. Site characteristics and lidar data collection information (Adapted from Dharmadasa et al. (2022))

	Sainte-Marthe	Saint-Maurice	Montmorency
Elevation range, m	70–78	46–50	670–700

Forest type	Deciduous	Mixed	Boreal

Mean canopy density, %	>80	60–80	60–80
Snow-on flight date	12 March 2020	11 March 2020	29 March 2019
Snow-off flight date	11 May 2020	02 May 2020	13 June 2019

MAAT= mean annual air temperature. Climatic data presented here were based on the climate averages (1981–2010) at the nearest Environment and Climate Change Canada (2021b) meteorological stations to the sites (Station climate ID 7016470, 7017585, and 7042388 for Sainte-Marthe, Saint-Maurice and Montmorency). None of the snow-on flights were conducted right after a storm.

Although the lidar data acquisition years are different between agro-forested sites and boreal forest due to logistical reasons, the study years are representative of the long-term climatological conditions at the sites (Supplement Fig. S1), and hence allowed us for inter-site comparison of snow depths.

2.2 Data processing

All lidar surveys were performed with a GeoMMS system mounted onto a DJI M600 Pro UAV platform. The GeoMMS system is comprised of a Velodyne VLP-16 lidar sensor, a real-time dual-antenna global navigation satellite system (GNSS) aided inertial navigation system (INS) for precise heading, and a tactical MG364 inertial measurement unit (IMU). The nominal accuracy of the point cloud provided by GeoMMS is ±5 cm (RMS, root mean square) (Geodetics, 2018) whereas the nominal uncorrelated relative error of two lidar point clouds is approximately ±7 cm ($\sqrt{5^2 + 5^2}$). Flight paths for the surveys were prepared in UgCS flight control software (Sph-Engineering, 2019) and the flight parameters were optimized to reduce overall INS errors and maximize the mapping efficiency in the forested areas. Table 2~~Table 2~~ outlines the flight parameters and equipment settings used in surveys.

Raw lidar data sets collected from the flights were post-processed in Geodetics LiDARTool (Geodetics, 2019) with post-processing kinematic (PPK) correction. The PPK option regenerated a significantly more accurate trajectory file by combining the onboard GNSS data with GNSS base station data. Then, this post-processed trajectory file was merged with the raw laser data to produce a geo-referenced x,y,z point cloud. Noise removal was applied next. We also employed a trial-and-error, manual boresight calibration method to correct for boresight errors in the data, as recommended by the manufacturer (Geodetics, 2019). The final post-processed point clouds have a~~n~~ vertical absolute accuracy range of 3–6 cm and a relative accuracy range of 4–6 cm (Dharmadasa et al., 2022).

To classify the bare surface points, we used the multiscale curvature algorithm (Evans and Hudak, 2007) implemented in the commercial Global Mapper software (Blue Marble Geographics, 2020). Parameters of the algorithm were adjusted according to the vertical spread of the flight strips over open terrain, the local slope of the terrain and canals/streams, and the presence/absence of buildings. The reader is referred to Dharmadasa et al. (2022) for a comprehensive overview of the UAV-lidar system and post-processing of raw data.

Table 2. Flight parameters and equipment settings

Flight parameters		Equipment settings	
Flying speed	3 m s^{-1}	Wavelength	905 nm
Flight altitude	40 m AGL	Laser pulse repetition rate	18.08 kHz
Field of view (horizontal)	145°	Field of view (vertical)	±15°
Distance between parallel flight lines	64 m	Laser RPM	1200
Ground overlap	20 %	Return type	Dual
Point density	603 points m^{-2}		

2.2.1 Snow depth maps

Snow depth maps were ~~quantified~~ obtained by differencing winter (snow-on) and summer (snow-off) digital elevation models (DEMs) generated from bare surface points at each site. Bare surface points were aggregated to a grid resolution of 1.4 m using the binning method in Global Mapper (Blue Marble Geographics, 2020). This grid resolution was selected based on the manual snow depth sampling strategy used by Dharmadasa et al. (2022) to validate the snow depth maps ~~(five snow depth measurements were taken at each sampling location in a diagonal cross shape at 1 m apart, and the average of these five measurements was considered to represent a 1.4x1.4 m ($\sqrt{1^2 + 1^2}$) grid cell)~~ and aimed to minimize the effect of positional errors of the manual measurements made with GNSS. The manual sampling strategy consisted of five snow depth measurements taken at each sampling location in a diagonal cross shape at 1 m apart, and the average of these five measurements represents a 1.4x1.4 m ($\sqrt{1^2 + 1^2}$) grid cell. As final filtering, spurious negative snow depths were set to zero, as they are physically inconsistent and need to be filtered (Hopkinson et al., 2012). Negative snow depths accounted for a very small portion of the total area (<0.1 %) sampled and had a negligible effect on the statistics derived from the snow depth maps. The validation of UAV-lidar snow depths with manual measurements showed a RMSE of 0.079–0.160 m in the deciduous forested environment, and 0.096–0.190 m in the coniferous forested environment (Dharmadasa et al., 2022), which is comparable to previous efforts with UAV-lidar (Harder et al., 2016; Jacobs et al., 2021) and airborne lidar (Harpold et al., 2014; Painter et al., 2016). ~~When taking into account the 2–10 cm thick ice layer that was typically observed at the base of the snowpack in the deciduous environment which limited the penetration of the snow depth manual probe into the soil, and the positional errors due to the multipath effect in the coniferous environment, our UAV-lidar snow depths maps were deemed to be robust and to represent an improvement over previous studies. As well, the higher RMSE in the coniferous forested environment has a comparatively smaller impact due to the deeper snowpack observed at the site, i.e., the relative RMSE error (RMSE/mean snow depth) in the coniferous forested environment (0.068–0.135) is much lower than the relative error (0.321–~~

~~0.420) in the deciduous forested environment where the snowpack is shallower.~~ More details about the snow depth validation can be found in Dharmadasa et al. (2022).

2.2.2 Terrain metrics

To typify the terrain characteristics, we derived four variables from the summer DEM, i.e., elevation (*Elevation*), slope (*Slope*), aspect (*Aspect*), and topographic wind sheltering index (*TWSI*) at 1.4 m resolution (Supplement Fig. S2–S4). Topographic variables other than elevation need to be considered when studying areas that encompass a small elevation range (Zheng et al., 2016), such as our sites. *Elevation* was obtained directly from the DEM, while *Slope* and *Aspect* were derived using ArcGIS 10.2 software. *Slope* was calculated as the first derivative of the DEM, while *Aspect* was derived in two orthogonal components, i.e., west-east (*Aspect_WE*) and south-north (*Aspect_SN*) exposures. *Aspect_WE* (west-negative, east-positive) and *Aspect_SN* (south-negative, north-positive) were calculated directly as the sine and cosine of the aspect, respectively. The *TWSI* was produced using the RSAGA package in CRAN. This variable considers the sheltering effects of the local topography in the dominant wind direction. Several studies showed that *TWSI* is a good measure to characterize sheltering and exposure of the local terrain ~~which gives~~providing a reasonable representation of the local wind field and thus the redistribution of snow by wind (Winstral et al., 2002; Winstral and Marks, 2002; Plattner et al., 2004; Molotch et al., 2005). Negative *TWSI* values correspond to terrain exposure and positive values to sheltering from the wind. Dominant wind directions were extracted from ~~the~~ hourly wind data for the ~~period 2019–2021~~study period considered (winter season in each study year as indicated in T~~t~~able 1) at each site (Fig. 2). Wind data was collected from an automatic weather station located 1.4 km away from the Sainte-Marthe site and the closest Environment Canada wind measuring stations at the other sites. The closest station to Saint-Maurice (climate ID 7018561) was 19 km away from the site and 0.25 km away from the Montmorency site (climate ID 7042395) (ECCC, 2021a).

Formatted: Font: Not Bold, Complex Script Font: Not Bold

2.2.3 Vegetation descriptors

Vegetation-related variables were rasterized from the classified winter point cloud in LiDAR360 (Greenvalley-International, 2020). The forestry module of LiDAR360 contains tools that allow users to calculate essential forest metrics and accurately extract individual tree parameters like crown diameter, crown area, and tree diameter by breast height from airborne lidar data. In this study, the leaf area index (*LAI*), canopy cover (*CC*), and gap fraction (*GF*) were estimated at 1.4 m resolution for the forest cover higher than 2 m (Supplement Fig. S2–S4). A 2 m height threshold was selected as canopies >2 m ~~have~~has been shown to have a strong influence on snow accumulation (Varhola et al., 2010b; Zheng et al., 2016; Zheng et al., 2019). The function used to calculate *LAI* is based on the Beer-Lambert law (Richardson et al., 2009). The estimated *LAI* is contingent on the average scan angle, *GF*, and ~~the~~ extinction coefficient. *GF*, the amount of open area within the canopy~~,~~ which is not blocked by branches or foliage, is calculated as the total number of ground points to the total number of lidar points within a grid cell. *CC*, which is defined as the percentage of vertical projection of forest canopy to the forest land area (Jennings et al., 1999), is calculated as the total number of vegetation returns to total returns (Morsdorf et al., 2006), (*CC* = 1 – *GF*). Refer to Richardson et al. (2009) and Morsdorf et al. (2006) for the equations used by LiDAR360 to estimate the forest metrics. In addition, canopy height (*CH*) was derived by subtracting the DEM from the digital surface model (DSM). ~~For rasterizing, a grid cell size slightly larger than the maximum individual crown diameter was selected to ensure that at least one tree was present within a grid cell (Li et al., 2012; Greenvalley-International, 2020). Grid resolutions obtained using this method were 20, 15, and 10 m in Sainte-Marthe, Saint-Maurice, and Montmorency, respectively.~~

Formatted: Font: Italic, Complex Script Font: Italic

2.2.4 Site variable

~~Apart from the derived variables mentioned in section 2.2, a~~A binary variable, ~~(~~*Site*~~)~~ representing forested (1), and field (0) pixels was ~~included in the regression analysis~~derived to investigate systematic effects, if any, of land cover that was not captured by vegetation or terrain metrics (Supplement Fig. S2–S4). This variable was derived by manually mapping field and forested area boundaries at each site in ArcGIS 10.2 software. After delineating forest and field boundaries, the area inside the forest boundary was assigned a value of 1, and the area inside the field boundary was assigned a value of 0.

~~2.2.4~~2.2.5 Forest edge descriptors

We investigated forest edge effects on snow accumulation using an approach inspired from Currier and Lundquist (2018) and Mazzotti et al. (2019) using Matlab software. Analogous to their ~~analysis~~analyses, we added directionality to forest edges to examine if preferential snow accumulation occurred windward or leeward of forest edges due to snow redistribution by wind or reduced ablation due to shading from the forest. Pixels were first classified as north-facing (*NFE*) when they were within a maximum search distance d_{max} northward of the forest edge. Forest edges (the boundary between field and forest areas) were extracted from the *Site* variable. Based on previous results by Currier and Lundquist (2018), d_{max} was set to 2H, where H is the typical tree height derived from the ~~1.4 m resolution~~ canopy height model at each site. The 2H distance reflects the typical

Formatted: Font: Italic, Complex Script Font: Italic

shading of the ground by the canopy. H is 15 m in Sainte-Marthe, 20 m in Saint-Maurice, and 12 m in Montmorency. A tolerance of ±45° was used for the search direction for *NFE*. Pixels were further classified as windward (*WFE*) and leeward (*LFE*) when they were within a maximum search distance of the forest edge in the dominant wind direction. A range of search directions was used to constrain the dominant wind directions at each site, based on wind roses (Fig. 2). Two dominant wind cones, 270±15°, and 50±15° were used in Sainte-Marthe, and one dominant wind cone in Saint-Maurice (210±15°) and Montmorency (310±15°). ~~D~~d_{max} was initially varied between 6–10H for pixels in open terrain based on Currier and Lundquist (2018), which represents the typical length scale of preferential snow accumulation at the forest edge. After a few trials, a final value of 10H was retained, which showed the highest correlation with snow depth. Moreover, the 10H distance at each site (150 m, 200 m, and 120 m in Sainte-Marthe, Saint-Maurice, and Montmorency respectively) encompassed the preferential snow accumulation seen along the forest~~ed~~ edges on the lidar-derived snow depth maps. A maximum search distance of 1H was used for pixels within the forest in order to detect if preferential accumulation from blowing snow penetrated the forest. This value was chosen based on visual observations in the field, which suggested limited penetration of blowing snow inside the forest. Figure 3 shows a ~~scehmatic~~schematic~~n~~ illustration of the forest edge parameters described.

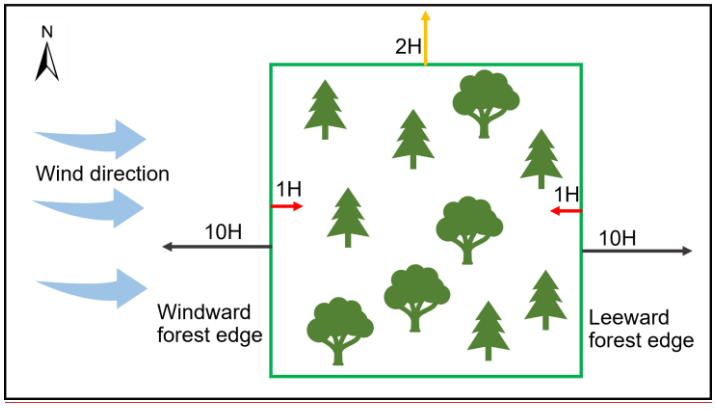

Figure 3. ~~G~~Graphical illustration of forest edges and respective maximum search distances, ~~d~~d_{max}. 10H indicates the maximum search distance in the open field from the forest edge in windward and leeward direction, 1H indicates the maximum search distance in the forest from the forest edge in the windward and leeward direction, and 2H indicates the maximum search distance northward of the forest edge, for shading effects.

A ~~novel~~ new index of proximity to the forest edge, *FE*, was calculated by scaling the distance between each pixel and the forest edge (d) by the maximum search distance, d_{max}:

$$FE = \frac{d_{max} - d}{d_{max}} \quad (1)$$

FE (either *NFE*, *WFE*, or *LFE*, depending on the initial classification) is equal to one when a pixel is situated on the forest edge and equal to zero when it is located at, or beyond the maximum search distance d_{max}. The novelty of this approach is to

derive a continuous predictor of forest edge proximity, as opposed to the simpler binary classification introduced by Currier and Lundquist (2018). Maps of the forest edge descriptors for each site can be found in supplement Fig. S2–S4.

2.3 Data analysis

Data analysis was primarily focused on assessing the small-scale snow depth heterogeneity at the selected sites. Lidar-derived snow depth data were analyzed for inter (agro-forested versus coniferous) and intra (field versus forest) site variability. First, the scale dependence of snow depth variability was explored using semi-variogram analysis. Then, the site-specific topographic and vegetation control on the snow depth spatial heterogeneity was examined with RF regression models. All the statistical analyses were performed in R software.

2.3.1 Spatial correlation analysis

To analyze the small-scale spatial variability of the snow depth map in each study site, omnidirectional semi-variograms were used. Semi-variogram analysis allows constraining the dominant scales of snow depth variability and to compare them between land cover types and sites. Canals/streams were discarded from the snow depth maps for this analysis to ensure stationarity of the surface. i.e., snow depths in canals/streams would have a unidirectional spatial correlation which could alter the relationship of the overall terrain by introducing biases. In addition, omnidirectional semi-variograms of snow depth were compared with those obtained from bare earth topography and topography+vegetation (DSM) surfaces to investigate the influence of topography and vegetation interactions on snow depth. Moreover, directional semi-variograms of snow depth were also computed to establish possible influences of dominant wind directions on snow depth variability at each site.

The semi-variogram $\gamma(r)$ is expressed as:

$$\gamma(r_k) = \frac{1}{2N(r_k)} \sum_{(i,j)\in N(r_k)} \{z_i - z_j\}^2 \quad (2)$$

Where r is the lag distance of bin k, $N(r_k)$ is the total number of pairs of points in the k^{th} bin and z_i and z_j are the snow depth values at two different point locations i and j (Webster and Oliver, 2007).

Half of the maximum point pairs distance (Sun et al., 2006) was taken as the maximum lag distance for the semi-variogram calculations with ~~We used~~ 50 log-width bins ~~for the semi-variogram analysis~~. Log-width distance bins provide equal bin widths when semi-variograms are transformed to log-log scale, and help resolve the semi-variogram at short length scales by allowing greater bin density at shorter lag distance compared to linear-width bins (Deems et al., 2006).

In the case of scale invariance, the semi-variogram can be described by a power law:

$$\gamma(r) = ar^b \quad (3)$$

Where a and b are coefficients selected to minimize the squared residuals.

To identify scale breaks in semi-variograms, the following steps were implemented following a similar approach suggested by Mendoza et al. (2020a).

- First, a change point analysis was conducted on the semi-variograms in log-log space using the ecp package in R (James and Matteson, 2014) to identify possible break points, which allows delineating sections of the semi-variogram with similar trends. ~~i.e., possible break points indicate that each cluster of variogram points separated by these break points shares a similar trend.~~
- Then, linear least square regression models were fitted in log-log space for each cluster of points identified in step 1~~of variogram points~~.
- Finally, we checked whether the changes in the slopes of the log-log linear models ~~are~~were larger than 20 % and that the 95 % confidence limits of the slopes di~~d~~o not overlap, and~~.~~ ~~Inspected visually in variogram of this scale break.~~ v~~V~~erified that the R^2 ~~is~~was greater than 0.9. If all these conditions ~~are~~were fulfilled, the existence of a scale break ~~is~~was confirmed.

2.3.2 Random forest model

To investigate the effect of vegetation and topographic variables on the spatial variability of snow depth, we applied RF regression models on the rasters derived from lidar data. Data were not separated into training and test sets so that we would not create an artificial bias by data splitting. i.e., all data at each site were used in the RF analysis. ~~Generally~~Generally, in a RF model, two-thirds of the sample data (in-bag) are~~is~~ used to train the model, while the remaining one-third (out-of-bag, OOB) is used to estimate how well the trained model performs ~~(as a validation set)~~. ~~These OOB observations are used to calculate predictor importance, which shows the relative contribution of each predictor (independent) variable to the response variable.~~ This in-bag and OOB sampling procedure is akin to the much used k-fold cross-validation approach (Probst and Boulesteix, 2017; Tyralis et al., 2019). ~~In general, the RF algorithm provides~~As such, model performance statistics (mean square error, MSE and variance explained) are derived from ~~by using~~ the OOB predictions. The RF algorithm also calculates the predictor importance (importance of a variable), by estimating how much the prediction error increases when OOB data for the respective variable is permuted while all others are left unchanged (Liaw and Wiener, 2002).

~~To have a consistent grid resolution in the analysis, the snow depth, terrain metrics, and *CH* were aggregated to the grid resolution of the vegetation descriptors. Thus, t~~The RF analyses were conducted in R with grid resolutions of ~~20~~ 1.4 m at all sites~~, 15 m, and 10 m in Sainte-Marthe, Saint-Maurice, and Montmorency, respectively~~. ~~Apart from the derived variables mentioned in section 2.2, a binary variable (*Site*) representing forested (1), and field (0) pixels was included in the regression analysis to investigate systematic effects, if any, of land cover that was not captured by vegetation or terrain metrics.~~ As a precautionary measure, we ~~also~~ excluded collinear variables prior to building the RF models using the variance inflation factor (VIF) function in R. This was done mainly because our objective was to investigate the relative contribution of different variables to snow depth variability in forest versus the field, rather than deriving a model with maximum predictive capacity. While RF can handle collinearity in a predictive mode, collinearity makes it difficult to separately evaluate the predictive power (variable importance) of the predictors (Bair et al., 2018). The number of trees in the ensemble (ntree) and the number

of variables at each node (mtry) were tuned before ~~optimized for~~training each RF model. RF model results ~~are~~ were first examined for ~~presented according to~~ the relative importance of predictor variables (variable importance ~~plots~~), which has proven to be useful for evaluating the relative contribution of input variables (Tyralis et al., 2019). ~~The value of the variable importance of a variable reflects how much removing this variable would decrease the accuracy of the model and vice versa.~~ Then the partial relationships of the variables with the snow depth were examined and presented. Partial dependence functions are typically used to help interpret models produced by machine learning models such as RF, ~~analysis~~ (Jerome, 2001). It is a risk-adjusted alternative to variable dependence. Each partial plot presented here was generated by integrating out the effects of all variables beside the covariate of interest. Partial dependence data in each plot were constructed by selecting points evenly spaced along the distribution of the variable of interest. This subsampling helps to cut down computational time substantially. We used the default subsampling of 51 points in our analysis. ~~Finally, t~~The performance of RF models in terms of ~~validation~~ OOB statistics ~~(OOB)~~ was compared between the different land cover types and sites and presented next.

Additionally, we discuss RF model performances compared to traditional MLR models, as well as ~~and~~ the relationships between snow depth and physiographic variables derived from RF~~M~~ models at~~at~~ 1.4 m resolution (sub-canopy resolution) versus ~~with that of the~~ single-tree scale at each site. Single-tree scale, as the name implies, is selected as the grid size that encompasses a single tree. This differed between the sites and was estimated in LiDAR360. We used the point cloud segmentation algorithm developed by Li et al. (2012) in LiDAR360 to segment individual trees and obtain their attributes such as tree location, tree height, crown diameter, and crown area. Then, the maximum crown diameter of the segmented trees in each site was selected as the single-tree scale grid resolution. Single-tree scale resolutions obtained using this method were 20, 15, and 10 m in Sainte-Marthe, Saint-Maurice, and Montmorency, respectively. ~~For rasterizing, a grid cell size slightly larger than the maximum individual crown diameter was selected to ensure that at least one tree was present within a grid cell (Li et al., 2012; Greenvalley International, 2020). Grid resolutions obtained using this method were 20, 15, and 10 m in Sainte-Marthe, Saint-Maurice, and Montmorency, respectively.~~

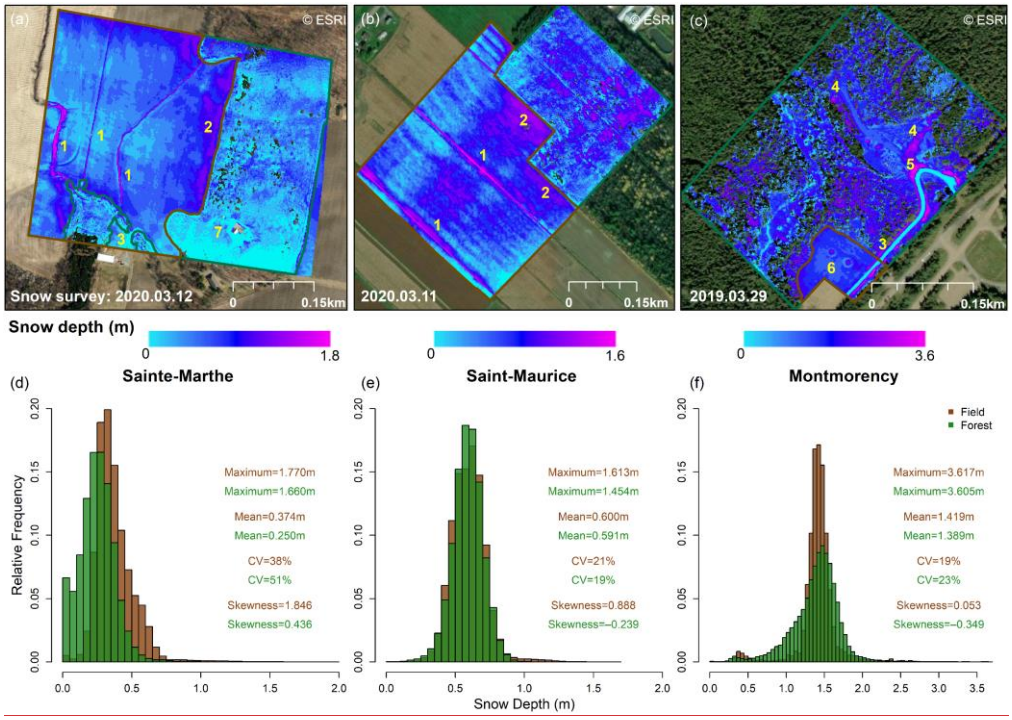
3 Results

3.1 General snow accumulation patterns

~~Figure 3~~Figure 4 depicts the snow depth maps derived from UAV-lidar data at the study sites. Montmorency shows the highest overall snow accumulation with a maximum of ~~3.7~~3.6 m. Higher snow accumulation in canals/streams (area 1 in ~~Fig. 3~~Fig. 4a, b) and along the forest edge (area 2 in ~~Fig. 3~~Fig. 4a, b) is evident in Sainte-Marthe and Saint-Maurice, whereas in Montmorency, forest gaps (area 4 in ~~Fig. 3~~Fig. 4c) seem to accumulate more snow. The highest snow depth in Montmorency corresponds to localized, artificial snow piles adjacent to the main road as observed during the field campaign (area 5 in ~~Fig. 3~~Fig. 4c). Concentric snow accumulation patterns around the double fence precipitation gauges are also noticeable in Montmorency snow depth map (area 6 in ~~Fig. 3~~Fig. 4c). Compared to the other two sites, the Montmorency snow depth map

comprises more data gaps in the forested area. Paved roads in Sainte-Marthe (area 3 in ~~Fig. 3~~Fig. 4a) and Montmorency (area 3 in ~~Fig. 3~~Fig. 4c) and the area surrounding the small house (area 7 in ~~Fig. 3~~Fig. 4a ~~and Fig. 3d~~) in the forest at Sainte-Marthe appear snow-free due to the snow clearing operations, as confirmed in field campaigns. Snow clearing in the proximity of the house in Sainte-Marthe accounts for a significant portion of zero and/or small snow depths (~~Fig. 3~~Fig. 4d) and biases the mean snow depth in the forest. When this portion is discarded, the mean snow depth in the forest increases from 0.~~246~~ 250 to 0.275 m. ~~Hence i~~In Sainte-Marthe, the mean snow depth in the field area is higher than that in the adjacent forested area (~~Fig. 3~~Fig. 4d), whereas, at the other two sites, mean snow depths in the field and forest are similar considering the measurement error of the lidar system (~~Fig. 3~~Fig. 4e, f). ~~We also used the~~A nonparametric Wilcoxon rank-sum test (Wilcoxon, 1945) ~~to~~was applied to test whether snow depths within forested and field areas were statistically different from each other. To remove spatial autocorrelation, snow depths were subsampled every 20 m (larger than the scale break distances found by semi-variogram analysis, Fig. 5). ~~Test~~The results ~~shows~~confirmed that snow depth in the Sainte-Marthe field was statistically greater than that in the forest and in the other two sites differences were not statistically significant.

Although the maximum snow depth is higher in Sainte-Marthe (~~1.~~91.8 m) compared to Saint-Maurice (1.6 m), snow depths in Sainte-Marthe ~~(0.246–0.369 m)(mean snow depths of 0.250–0.374 m, in forest, and field respectively) appear to be~~are lower on average (mean forest = 0.250 m; mean field = 0.374 m) than in Saint-Maurice ~~(0.592–0.600 m)~~ (mean forest = ~~snow depths of~~ 0.591 m; mean field = 0.600 m~~, in forest, and field respectively~~). The snow depth is more variable in the forest (higher~~Higher~~ coefficient of variation, CV) than in the field ~~(CV) values~~ in Sainte-Marthe and Montmorency ~~forests infer a greater dispersion in snow depth distributions than in the field~~, which is not the case in~~.~~ Saint-Maurice, where the coefficient of variation in the field is slightly larger than in the forest~~. snow depth distribution shows the opposite, but the difference between field and forest is not significant compared to the other two sites.~~



370 **Figure** ~~43~~. UAV-lidar derived snow depth maps (grid size 1.4 m) and histograms of snow depth distribution. **(a, d)** Sainte-Marthe map with snow surveying date and histogram; **(b, e)** Saint-Maurice map with snow surveying date and histogram; **(c, f)** Montmorency map with snow surveying date and histogram. Field and forest areas are demarcated with brown and green colors in snow depth maps respectively. Histograms are derived according to these boundaries. Features 1 to 7 are discussed in the text.

3.2 Spatial correlation analysis

375 Omnidirectional semi-variograms of snow depth, bare earth topography, and topography+vegetation surface at the study sites are shown on a log-log scale in Fig ~~4~~5. Semi-variograms were discretely developed for field and forested areas to assess the effect of land cover on the snow depth variability. Overall, forested areas show more variable (higher semi-variance values) snow depths than field snow depths at all sites. Snow depths seem to be more variable in ~~the~~ coniferous forests than in deciduous and mixed forests. Snow depth in ~~F~~forested areas at all three sites shows a typical ~~multifractal~~ multi-scaling
380 behavior, where the semi-variance between neighboring snow depths increases rapidly up to a scale break located at distances less than 10 m (Fig. ~~4~~5a, b and c), followed by a slower increase thereafter. ~~The Sainte-Marthe field area does not exhibit a distinct scale break. In contrast, both Saint-Maurice and Montmorency field areas show multiscale behavior.~~ Similarly, field

snow depths exhibit multi-scaling behavior with comparatively larger scale break distances, ~~whereas~~with Montmorency showing~~ing~~ two scale break distances (Fig. 5a, b and c). Topography+vegetation surfaces show the highest semi-variance with scale break distances ~~of~~ similar ~~magnitudes as~~to forest snow depths (Fig. 5d, e and f). Sainte-Marthe bare earth topography does not exhibit a distinct scale break (Fig. 5d). In contrast, the ~~the other two sites'~~ bare earth topography at the ~~the~~ other two sites shows multi-scaling behavior with scale break distances larger than 10 m (Fig. 5e, f).

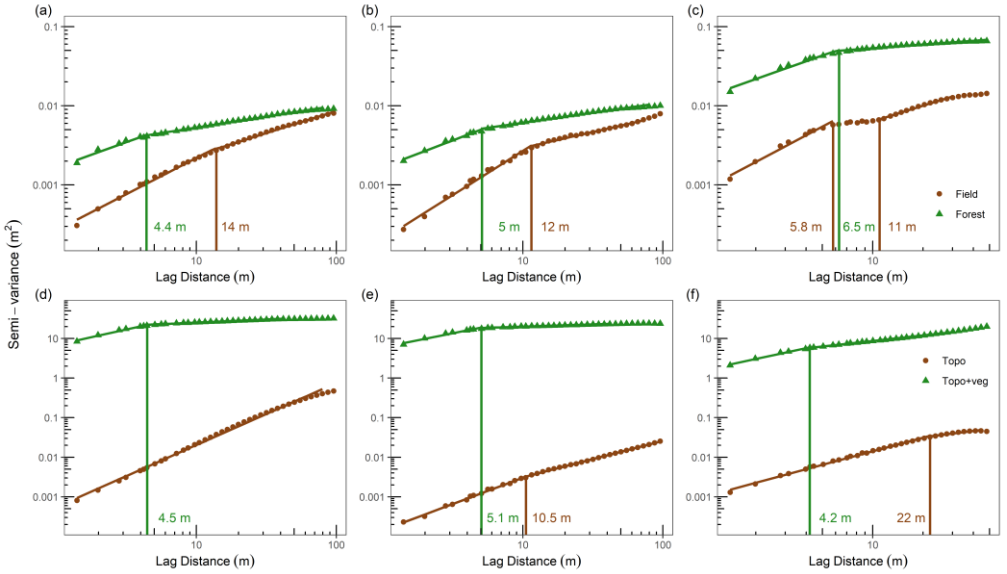


Figure 5~~4~~. ~~Omnidirectional semi-variogram for the field and forested areas at (a) Sainte-Marthe, (b) Saint-Maurice and (c) Montmorency. Vertical lines indicate the dominant scale breaks.~~Omnidirectional semi-variogram for the field and forested areas for **(a)** Sainte-Marthe snow depth, **(b)** Saint-Maurice snow depth, **(c)** Montmorency snow depth, **(d)** Sainte-Marthe bare earth topography and topography+vegetation, **(e)** Saint-Maurice bare earth topography and topography+vegetation and **(f)** Montmorency bare earth topography and topography+vegetation. In the figure, Topo denotes bare earth topography and Topo+veg denotes topography+vegetation surface. Vertical lines indicate the dominant scale breaks, and ~~diagonal~~trend lines represent significant (p<0.05) log-log linear models with $R^2 > 0.9$ (see methods).

Figure 6 shows directional semi-variograms of snow depth derived for field and forested areas at each site. Sainte-Marthe field snow depths show an isotropic behavior (Fig. 6a) whereas Sainte-Marthe forest shows an anisotropic behavior along the west-east direction (Fig. 6d). In contrast, both Saint-Maurice field and forest snow depths show distinct anisotropic behaviors. Saint-Maurice field snow depths show a narrow anisotropic pattern along northwest-southeast and a broad anisotropic pattern along southwest-northeast directions (Fig. 6b) whereas forest snow depths show an anisotropic pattern along southwest-northeast direction (Fig. 6e)~~at directions~~. Neither field nor forest snow depths in Montmorency show strong anisotropic behavior (Fig. 6c, f).

3.3 Random forest analysis

3.3.1 Potential predictors of RF model

~~We discarded~~ *Elevation* was discarded from the analysis since the elevation ~~difference~~ range at ~~any of the three~~all sites was too small (Table 1) to produce any meaningful local orographic effect on precipitation, or adiabatic effects on air temperature, e.g., Mazzotti et al. (2019), and could mask other local topographic effects on accumulation related to slope, aspect and terrain roughness (wind sheltering), due to collinearity. ~~And~~In addition, irrespective of the variable type, ~~we excluded~~ collinear

variables were identified and discarded prior to building the RF models inat all sites. As such, the topographical variables *Slope*, *Aspect_WE*, *Aspect_SN*, and *TWSI* were*TWSI* were used at all sites. However, the vVegetation descriptors (*LAI*, *CC*, *GF*, and *CH*) were strongly intercorrelated (with correlation coefficient, r of 0.82–1.00) and hence could not be used together in a predictive model, –(at least not without compromising the interpretation of variable importance in the RF model). Therefore, *LAI* was selected as the most representative forest structure indicatorto use in the RF analysis as, it has been shown to be a strong predictor of snow accumulation in forests (Hedstrom and Pomeroy, 1998; Pomeroy et al., 1998; Broxton et al., 2015; Lendzioch et al., 2016). Moreover, a sensitivity analysis showeds that the choice of forest structure descriptor has a negligible impact on the performance (R^2) of RF models (Supplement Table S1). The sSelection of the windward and leeward forest edge descriptors (*WFE* and *LFE*) was guided by the landscape setting at each site. In Sainte-Marthe, both *WFE* and *LFE* have large extents (Supplement Fig. S2) but are collinear due to the two dominant and opposed wind directions. Including both variables in the RF model would thus compromise the interpretation of the variable importance. Hence, we opted to use the *WFE* only in the final RF analysis. In Saint-Maurice, *LFE* has only a few pixels (Supplement Fig. S3) and was hence omitted from the RF analysis. In Montmorency, *LFE* seemingly has more influence on snow depth variability with its larger extent than the *WFE* (as shown in Supplement Fig. S4). This is also more logical as the open areas in Montmorency constitute a large gap within an overall forested environment, so deposition is expected leeward of the forest edge with little remobilization (erosion) within the gap. *NFE* was used at all sites to see the effect of forest edge shading on the snow depth variability. The variables used in RF analysis at each site following this procedure are, in Sainte-Marthe: *Slope*, *Aspect_WE*, *Aspect_SN*, *TWSI*, *LAI*, *WFE*, and *NFE*, in Saint-Maurice: *Slope*, *Aspect_WE*, *Aspect_SN*, *TWSI*, *LAI*, *WFE*, and *NFE*, and in Montmorency: *Slope*, *Aspect_WE*, *Aspect_SN*, *TWSI*, *LAI*, *LFE*, and *NFE*.

. As well, *LFE* was found to have a negligible influence on snow depth, hence was also excluded from the list of potential predictors. *CC* and the binary *Site* variable were further excluded due to collinearity issues. Collinearity analysis suggested discarding *GF* and *CH* in favor of *LAI* at the two agro-forested sites, while *LAI* was instead flagged as colinear instead of *GF* and *CH* in the coniferous site. Since *LAI*, *GF* and *CH* are strongly intercorrelated (r = 0.84–0.97), and because *LAI* has been shown to be a strong predictor of snow accumulations in forests (Hedstrom and Pomeroy, 1998; Pomeroy et al., 1998; Broxton et al., 2015; Lendzioch et al., 2016) we chose to retain *LAI* as a common forest metric and discard *GF* and *CH* to allow for a better intercomparison of the snow depth variability with vegetation across all three sites. The final potential predictor variables retained for all three sites were *Slope*, *Aspect_WE*, *Aspect_SN*, *TWSI*, *LAI*, *WFE*, and *NFE*.

3.3.2 Relative importance of topography and vegetation on snow depth variability

The relative importance of predictor variables in Fig. 57, scaled between 0 and 1, summarizes the relative contribution of the different topographic, vegetation, and forest edge effects on snow depth spatial variability at each site. At the full domain (field+forest), The windward forest edge proximity (*WFE*) has the strongest influence on snow depth variability in both Sainte-Marthe (50 %0.99) and Saint-Maurice (76 %0.97) when both landscape units (field+forest) are combined, and the north-facing

forest edge proximity ~~index~~ (*NFE*) has the least influence (~~12 %~~0.30 and ~~10 %~~0.23). However, topographic wind sheltering (*TWSI*) exerts an equally strong impact on snow depth as *WFE* in Sainte-Marthe (0.99) compared to that in Saint-Maurice (0.70). In Montmorency, *LAI* and ~~*WFE NFE* respectively~~ have the highest (~~64 %~~0.99) and least (~~3 %~~0.07) impacts, respectively, on snow depth variability for the ~~combined landscape unit~~full domain. The importance of variables somewhat changes when forests and fields are modelled independently, implying different dominant factors/processes acting in ~~forests and fields~~such environments. For instance, in Sainte-Marthe, the ~~northern exposure (*Aspect_SN*)~~*TWSI* seems to be the dominant variable (~~31 %~~0.74) for snow depth variability in the forest followed by ~~*TWSI LAI* (28 %~~0.36), ~~*Slope WFE* ((22 %~~0.36), and ~~*LAI Slope* (17 %~~0.31). In Sainte-Marthe field, *WFE* (~~58 %~~0.94), *TWSI Slope* (~~25 %~~0.87), and *Slope TWSI* (~~25 %~~0.62) are the most important variables. *WFE* (~~13 %~~0.33), *TWSI* (~~13 %~~0.25), and *LAI* (~~6 %~~0.21) have the highest influence on snow depth within the Saint-Maurice forest whereas in the adjacent field *WFE* (~~69 %~~0.99), *TWSI* (~~39 %~~0.64), and *Slope* (~~33 %~~0.39) predominate. The importance of *LAI* (~~73 %~~0.97), *TWSI* (~~28 %~~0.41), and ~~*Aspect_WE*~~*Slope* (~~20 %~~0.25) is higher for snow depths within the coniferous forest with gaps in Montmorency, whereas the snow depths in the small field are mostly influenced by *LFE* (0.27), *TWSI* (0.23), and *Slope* (0.18). ~~*NFE* (15 %), *Aspect_SN* (12 %), and *LAI* (9 %).~~

3.3.3 Partial relationships of predictor variables with snow depth

As seen in Fig. ~~6~~8, all variables exhibit mostly~~a~~ non-linear relationships with snow depth across all sites. ~~We report S~~spearman rank correlation coefficients (ρ) were used to quantify the strength of the partial relationships and reported in the graphs~~to provide a quantitative presentation of the correlation of predictor variables with snow depth~~. A positive ρ indicates an increasing monotonic trend and a negative ρ indicates a decreasing ~~trend~~one. Note that the positive *LAI* values in field areas correspond to a few isolated *LAI* pixels along the forest edges, the boundary between field and forest. ~~The following sections describe the results obtained at each site.~~ In general, ~~in~~at all sites and~~,~~ despite ~~having strong (high ρ value) or weak (low ρ value) correlation with snow depth~~the magnitude of the correlation, the two slope ~~orientations~~ aspect variables (*Aspect_WE*

and *Aspect_SN*) ~~and~~as well as forest shading represented by the north-facing forest edge proximity (*NFE*) have the least effect on snow depth change (i.e., ~~small difference in snow depth, i.e., graphs are almost flat~~a relatively flat partial relationship on Fig. 8). Moreover, all the ~~, all overall (field+forest curves)~~ relationships between ~~variable~~landscape descriptors and ~~-~~snow depth for the overall domain in Montmorency (field+forest, blue curves on Fig. 8) ~~relationships~~, except *NFE*, ~~in Montmorency~~ are governed by the respective variable behavior in the forest, probably due to the large extent of forest ~~in~~at this site (Fig. 8c). With regards to topographical control, a~~A~~ll sites show increasing snow depths with increasing slopes in the field, forest, and field+forest (positive ρ values in Fig. 8a, b, and c ~~in Slope graphs~~). The general relationship of snow depth with *TWSI* suggests that increased topographic sheltering from the wind (increasing *TWSI* values), leads to ~~higher~~enhanced snow accumulation. ~~In~~At the two agro-forested sites (Fig. 8a, b), the greatest contribution to the overall field+forest *TWSI*-snow depth relation comes from field snow depths.

As for the influence of vegetation, t~~T~~here is a decrease in snow depths in response to increasing *LAI* at all sites, although the relation is comparatively weak (ρ =~~-~~ 0.65) in the Sainte-Marthe forest. Snow depth ~~in~~at the two agro-forested sites shows a general~~n~~ increase~~s~~ in response to ~~in response to~~ increasing distance towards the windward forest edge (*WFE*), except ~~in~~within the Saint-Maurice forest. An increase of snow depth with *WFE* in Sainte-Marthe forest indicates more snow at the edge and decreasing inward the forest, which reflects blowing snow penetration from the field inside the forest. The ~~slight~~ increase in snow depth with *WFE* within the Sainte~~However, the increase of snow depth with increasing *WFE* in Sainte-Marthe forest and, the same behavior in Saint~~-Maurice forest ~~after~~for *WFE* >~~of~~ ~0.8 could also reflect the limited penetration of~~be a result of a limited~~ blowing snow ~~penetration~~ from the field inside the~~to~~ forest ~~near the forest edge~~. In Montmorency, the field snow depth shows a non-linear relation with *LFE*, probably due to the influence of instrumentation ~~and~~while forest snow depths show a ~~slight~~ decrease in accumulation inward ~~from~~ the forest ~~edge~~ .

~~***Sainte-Marthe***~~

~~The mild slopes of this site do not show a strong relationship with snow depths in field+forest and forest, but field snow depths show a slight increase at higher slopes (Fig. 6a). There is no apparent preferential accumulation of snow on either west or east-facing slopes (*Aspect_WE*). However, snow seems to accumulate preferentially on northern exposed slopes, especially within the forest (*Aspect_SN* graph in Fig. 6a). The general relationship of snow depth with *TWSI* suggests that increased topographic sheltering from the wind (increasing *TWSI* values), leads to higher snow accumulation. There is a decrease in snow depths in response to increasing *LAI* for the combined field+forest and within the forest, though the relation is weak in the forest, with snow depth increasing up to a *LAI* of 0.5 which could reflect the forest edge transition, and decreasing afterward. Snow depth in the field and field+forest increases in response to increasing *WFE*, whereas snow depth in the forest does not show any significant change. *NFE* does not show a substantial effect on snow depths.~~

Snow depths in Saint-Maurice (Fig. 6b) seem to increase with increasing slopes in the field while the reverse relationship is seen in the forest for higher slopes. There is a slight increase in snow depth from westerly to easterly slopes in the forest, ending with a sharp decrease for easterly slopes in the forest (*Aspect_WE*>0.5), due to fewer easterly pixels in the forest (Supplement Fig. S2). Field snow depths show a slight increase from west to east aspects but do not show any visible dependence on south-north aspects. Similar to Sainte-Marthe, snow accumulation in the forest is favored on northerly slopes. Snow depth shows a general increase in response to increasing *TWSI*, with the greatest contribution to this relation from field snow depths. A non-linear decrease of snow depth with increasing *LAI*, stronger than that seen in Sainte-Marthe, is clearly visible in Saint-Maurice. However, contrary to Sainte-Marthe, the overall relationship is dominated by intra forest variations in *LAI* rather than the difference between the field and forest. Field and field+forest snow depths show a similar pattern to Sainte-Marthe with an increase in response to *WFE*. On the contrary, forest snow depth shows a slight decrease with increasing *WFE*. However, snow depth in the field shows an increase in more northerly oriented forest edge pixels (*NFE*).

Montmorency

Slopes in the Montmorency forest (Fig. 6c) seemingly govern the overall snow depth-*Slope* relationship in this site. Snow depths increase linearly until *Slope* reaches ~5° and then remain nearly constant afterward. There is no apparent preferential accumulation of snow on either west or east-facing slopes (*Aspect_WE*). Contrary to other sites, Montmorency forest does not show any preferential snow accumulation on northerly or southerly slopes, but field slopes with southern aspects seemingly accumulate higher snow depths than northern aspects. Forest *TWSI* appears to govern the overall snow depth-*TWSI* relationship, probably due to its larger extent compared to the other sites. The range of *TWSI* values in Montmorency, especially the positive (sheltering) ones, are much higher than in the other two sites, due to the more rugged topography in Montmorency. The snow depth-*TWSI* relationship is complex, but generally shows a positive trend. This site shows a relationship of snow depth with *LAI* similar to the other sites, especially Saint-Maurice, with snow depth decreasing until *LAI* reaches ~1.5. *WFE* does not show a considerable effect on snow depths in Montmorency. However, snow depth in the field shows an increase in more northerly oriented forest edge pixels.

3.3.4 Performance of RF models at each site

Figure ~~7~~ 9 displays the ~~observed versus~~ RF model estimates versus observed ~~of the~~ snow depth with corresponding OOB statistics for each site. Statistics are presented individually for the field, forest, and ~~combined landscapes~~full domain (field+forest). Among the three sites, Sainte-Marthe RF model generally performs better with an OOB R^2 of ~~0.52~~0.66 and RMSE of 0.~~084~~ 083 m, and Montmorency shows the weakest performance with an R^2 of 0.~~28~~ 30 and RMSE of 0.~~160~~ 261 m. ~~Sainte-Marthe~~ All field models perform comparatively better with higher R^2 and lower RMSEs values than their forest models.~~field and forest models have similar R^2 and RMSE statistics (Fig. 7a), while Saint-Maurice field model performance is comparatively better (higher R^2 and lower RMSE, Fig. 7b) than that in the forest. On the contrary, Montmorency forest model performs better than that of the field (Fig. 7c).~~

4 Discussion

4.1 Spatial variability of forest versus field snow depths

Snow depths in ~~Fig. 3~~Fig. 4 show ~~a~~ remarkable microtopographic variability across all sites. Our results in Sainte-Marthe underpin the previous finding that forested areas accumulate less snow than the adjacent open areas due to canopy interception and sublimation losses and sheltering from wind (Pomeroy and Granger, 1997; Hopkinson et al., 2004; Varhola et al., 2010a; Zheng et al., 2018; Hojatimalekshah et al., 2021). But the other two sites show on average, a similar amount of snow accumulation in the field and forest. The dense coniferous canopy cover in Montmorency prevented laser shots from reaching

the ground at some locations and consequently ~~showed~~ resulted in ~~up as~~ data gaps in the snow depth map (~~Fig. 3~~Fig. 4c). The snow depth patterns in the coniferous site thus appear to be dominated by canopy closure, i.e., forest clearings have higher snow depths than adjacent canopies. Such patterns have been previously reported by both ALS and UAV-lidar studies in western alpine/pre-alpine environments with different climates (Hopkinson et al., 2004; Zheng et al., 2016; Mazzotti et al., 2019; Jacobs et al., 2021). The overall amount of snow in the forest compared to field in the boreal forest of Montmorency could thus be underestimated due to poor lidar coverage under dense canopies.

~~In~~ At the agro-forested sites, the comparatively higher snow depths observed in the open field compared to the adjacent forest patches are in contrast to what Aygün et al. (2020) observed in similar environments in southern Québec. They measured a lower snow accumulation in exposed agricultural fields (excluding the canals and the forest edge) compared to the adjacent deciduous and mixed forests. ~~In our results,~~Our results show that the higher snow depths ~~values~~ at the two agro-forested sites principally correspond to canals and ~~/~~streams ~~locations~~ in the field and the forest edge~~s~~, which trap the snow blown from the open field with greater fetches. Hence canals/streams and forest edges constitute the main structuring elements of snow spatial variability at these sites. However, if canals and forest edge snow depths are discarded, the agro-forested snow depth maps illustrate a somewhat similar phenomena to Aygün et al. (2020), where snow depths in the exposed field ~~appear to be~~are slightly lower than those in the forest. In Saint-Maurice, c~~C~~lusters of high snow depth values in the central area of the ~~Saint-Maurice~~ field in ~~Fig. 3~~Fig. 4b could be due to local redeposition of snow by the wind in the microtopography, or larger-scale effects. This could not be verified as unfortunately, the manual measurements in Saint-Maurice could not be retrieved due to a probe malfunctioning (Dharmadasa et al., 2022). Yet, the *TWSI* map (Supplement Fig. S3~~2~~) suggests that microtopographic wind sheltering could be the reason for the local snow deposition closer to the forest edge. ~~But t~~The probable cause for the other larger high snow depth cluster between the two streams in the field could not be ~~resolved~~ explained from the available ~~data~~predictors. They could be explained by the influence of the narrow riparian strips of bushes and shrubs surrounding the canals on blowing snow redistribution. ~~However~~Ultimately, as ~~the~~ canopy interception and losses in deciduous and mixed forests are expected to be small (Hopkinson et al., 2010; Aygün et al., 2020), the amount of differential snow depths between the open field and ~~shaded~~ forest would mostly depend on the amount of erosion in the field, and perhaps snowmelt losses in the open field prior to peak snow accumulation. ~~As well~~Moreover, ~~a visual comparison of the inter-site~~the snow depth maps suggests that the redistribution of eroded snow in fields ~~along snow accumulation~~ along the forest edges is a prime process in agro-forested landscapes.

4.2 Scaling characteristics of forest versus field snow depths

~~4.2~~4.2.1 Omnidirectional semi-variograms analysis

Formatted: Heading 3

Omnidirectional ~~S~~semi-variogram analyses revealed distinct scaling behaviors in forest versus field snow depths (Fig. ~~4~~ 5). Our results suggest a more variable (high semi-variance values) and more spatially continuous (larger scale break distance) snowpack in the Montmorency boreal forest compared to the temperate forest sites. The snowpack in the mixed forest at Saint-

Maurice was less variable and more spatially continuous than that in the Sainte-Marthe deciduous forest. Compared to forested areas, the snowpack in field areas was less variable and more spatially continuous. Shorter scale break distances in forested areas compared to open field areas (Fig. 45) is analogous to previous studies that studied the fractal distribution of snow depths with lidar data. ~~Previous~~ These studies reported scale break distances of 4 m for a shrub-dominated sparsely distributed subalpine site (Mendoza et al., 2020b), 7–9 m for high to moderately dense coniferous forests (Trujillo et al., 2007; Trujillo et al., 2009), 12 m for a moderately dense deciduous forest (Trujillo et al., 2007; Trujillo et al., 2009), 15.5 m for a dense coniferous forest with open meadows (Deems et al., 2006; Fassnacht and Deems, 2006), and 16.5 m for a sparse coniferous forest (Deems et al., 2006; Fassnacht and Deems, 2006). We found the shortest scale break distance of ~~4.1~~4.4 m for the dense deciduous forest in Sainte-Marthe, an intermediate distance of 5 m for the moderately dense mixed forest in Saint-Maurice, and a value of ~~7~~ 6.5 m for the dense coniferous forest interspersed with gaps in Montmorency. These values are rather smaller than those reported by ~~the~~ previous studies, except Mendoza et al. (2020b). This could be due to ~~inherent~~ structural characteristics of the forests such as canopy density and size of open areas (gaps). It is also plausible that the dense point cloud provided by UAV ~~(~150–600 points m^{-2},~~ (~150–600 points m^{-2}: Zhang et al., 2019; Harder et al., 2020; Jacobs et al., 2021; Dharmadasa et al., 2022)~~)~~ was able to resolve spatially distributed snow depth patterns at finer scales than that permitted by previous ALS surveys, which had typical point densities of ~8–16 points m^{-2} (Kirchner et al., 2014; Broxton et al., 2015; Broxton et al., 2019; Currier et al., 2019). However, similar to the findings reported by Deems et al. (2006) and Trujillo et al. (2007) our topography+vegetation surface data show scale break distances at the same order of magnitude as the forest snow depths at all sites. This indicates that the variability of vegetation (trees) governs the pattern of snow deposition and distribution within the forest (Deems et al., 2006).

The relatively higher scale break distance in Montmorency forest snow depth could be due to the prevailing large gaps in the forest as a result of silvicultural practices and ~~inherent~~ the higher efficient canopy interception of conifers. Coniferous trees have a substantial impact on snow depths as they intercept snow efficiently and unload it around the crown (Zheng et al., 2019). Thus, a longer correlation length (at least the diameter of a tree crown) is expected as well as greater variability of snow depth in ~~the~~ coniferous environments compared to the more random deciduous tree structures which have reduced and more transient snow storage (Mendoza et al., 2020b). Leafless deciduous trees aid faster unloading of snow through branches as opposed to unloading around the crown in conifers and thus ~~can~~ would result in a smaller correlation length in snow depth.

The difference in scale break distances in field snow depths compared to bare earth topography indicates that the bare ground surface in field areas was certainly altered by the snow accumulation. In Sainte-Marthe, snow accumulation increases the roughness of the bare ground whereas, in Saint-Maurice, snow accumulation results in a smooth surface compared to the ground underneath. i.e., interactions of snow with bare ground in Sainte-Marthe field change the scale invariance behavior to multi-scaling, and in Saint-Maurice, these interactions smooth the surface and resulted in a larger scale break distance than that of the bare ground. However, the~~a~~ larger scale break distance ~~with~~and ~~a less steep~~more gentle ~~-~~slope ~~in~~of the Sainte-Marthe field semi-variogram (Fig. 5a) ~~than~~compared to ~~that of~~ Saint-Maurice (Fig. 5b) suggests that the snowpack in Sainte-Marthe field is still smoother and more spatially continuous than that of Saint-Maurice. This interpretation is supported by the

Formatted: Superscript

snow depth map in Fig. 4a, which shows a smooth snow depth pattern that is only disrupted by preferential accumulation within irrigation canals/streams. In Montmorency field, rather than interactions of snow with bare ground, the meteorological station network appears to modify the snow accumulation and distribution patterns and resulted in different multi-scaling behavior than the bare ground. ~~The largest~~In general, large scale break distances (11–14 m) compared to forested areas ~~were~~ was found in ~~the Saint-Maurice~~ field ~~(18 m)~~ snow depths at all sites except the short, first scale break distance (5.8 m) in Montmorency. With the absence of vegetation in the field in winter and its high exposure to ~~the~~ wind ~~in~~at the two agro-forested sites (Fig. 2a, b), these~~is~~ values ~~is~~ are of similar magnitude to those reported for wind-exposed slopes in alpine environments (13.8–20.5 m) by Schirmer and Lehning (2011), Mott et al. (2011), ~~and~~ Mendoza et al. (2020a), and Mendoza et al. (2020b). In the Montmorency field, ~~being~~ mostly ~~wind~~ sheltered from the wind, the short and large scale break distances could be due to the influence of preferential snow accumulation near the meteorological equipment (e.g., concentric snow accumulations patterns around the two double-fenced precipitation gauges in Fig. 4c).~~Scale invariance in the Sainte-Marthe field suggests a more spatially continuous snowpack. This interpretation is supported by the snow depth maps in Fig. 3, which show a smooth snow depth pattern that is only disrupted by preferential accumulation within irrigation canals/streams. The comparatively smaller scale break distance in the Montmorency field (8.5 m) could be due to its small extent and the influence of preferential accumulation near the meteorological equipment (concentric snow accumulations patterns around the two double-fenced precipitation gauges in Fig. 3c).~~

Generally, the scale break distances found in this study suggest that the scale selected for modeling or sampling in similar environments should be well below these values, in order to represent the small-scale variability of the snow depth.

4.2.2 Directional semi-variograms analysis

Sainte-Marthe field snow depths di~~d~~o not show any directionality, most probably as a result of the interactions of snow with two dominant and opposed wind directions. In contrast, Saint-Maurice field snow depths showed anisotropic behaviors along and perpendicular to the dominant wind direction. Narrow anisotropic patterns perpendicular to the dominant wind direction are due to the snow accumulation alongside canals. Even though the canals were discarded in semi-variogram analysis, as seen from Fig. 4b, snow accumulation alongside the canal banks up to a few meters into the field is still significant. Broader anisotropic patterns along the dominant wind direction are due to the influence of wind. This directionality is also shown in the snow depth map in Fig. 4b, where the change of snow depth values along the direction perpendicular (northwest-southeast) to the dominant wind direction is more drastic than the change of snow depths along the dominant wind direction towards the forest. However, forest snow depths ~~in~~at both agro-forested sites show anisotropic behavior, although not very strong, parallel to dominant wind directions. This indicates an influence of blowing snow ~~wind blown from the open field to the forest~~ on the snow distribution patterns in the forest, and hence a possible ~~blowing snow~~ penetration of blowing snow from field to forest. The i~~I~~sotropic behavior in the Montmorency field and forest, on the other way, is not surprising given that the ~~site~~site is sheltered ~~by~~from the dominant winds (Fig. 2c).

4.3 Relationship of snow depth to topographic and vegetation characteristics

~~Our results affirm the non-linearity between snow depth and the variables considered and the importance of considering this non-linearity in statistical models.~~ During the analysis, some consistent patterns emerged between all three sites, which have been found in previous studies, i.e., snow depth generally decreases with an increase in *LAI* values (Varhola et al., 2010b), and snow depth increases with an increase of *TWSI* (Revuelto et al., 2014).

4.3.1 At the ~~a~~At a~~a~~gro-forested sites

~~In~~ At the two agro-forested sites, field snow depth variability is governed by ~~the~~ preferential snow accumulation in canals/streams and the microtopography of the local terrain. ~~In fact~~As such, the highest wind sheltering values were found in canals/streams which accumulated more snow (~~Fig. 3~~Fig. 4 and Supplement Fig. S~~1~~2, S~~3~~2). Within the forested areas, the influence of forest structure (*LAI*) was not as strong as expected; instead, the influence of microtopography appeared to be mostly governing the snow depth variability. The lower influence of *LAI* at these sites probably reflects the abundance of leafless trees in winter, which reduce interception losses and concurrent spatial snowpack variability. Moreover, the microtopography of these landscapes is closely related to the surficial geology of the sites. Preserved forested patches in the St. Lawrence River lowlands often correspond to less favorable soil conditions, such as glacial till and/or ~~with~~ bedrock outcrops and associated rougher microtopography. Conversa~~e~~ly, ~~Whereas a~~aA~~g~~ricultural fields are ~~associated~~ develo~~p~~pped ~~with~~ on glaciomarine or fluvioglacial sediments that are flatter in nature and also leve~~l~~led ~~exhibit even more flatter surface conditions because of~~ by machinery ~~usage~~ (MFFP, Québec Research and Development Institute for the Agri-Environment (IRDA) and La Financière Agricole du Québec (FADQ)). Under limited wind transport, ~~this~~ the rougher microtopography in forest~~sed surfaces~~ creates a directional bias that promotes lateral transport of snow particles (bounce/ roll/ ejection) and therefore enhances the smoothing of the snow surface (Filhol and Sturm, 2019) which~~and~~ dominate~~sing~~~~es~~ the snow heterogeneity within the forest. The absence of apparent preferential snow accumulation on different slope orientations in agricultural fields suggests a smoothening of the topography by the snow cover due to wind redistribution in the field. The m~~M~~ore rugged microtopography of the forested soil on the other hand seems to be preserved and to influence the snow cover through differential radiation loading, resulting in more snow accumulations on northerly slopes in the forest compared to that in the field (Fig. ~~6a~~8a, b).

At the ~~combined scale full domain~~landscape scale (field+forest), the agro-forested sites are dominated by blowing snow accumulation along the forest edges (Fig. ~~5a~~7a, b). This effect is well visible on the lidar-derived snow depth maps too ~~as well~~ (~~Fig. 3~~Fig. 4a, b). Comparatively high wind speeds and more constrained dominant wind directions (Fig. 2a, b) at these sites create favorable conditions for preferential deposition of blowing snow at the forest edge due to the large expanses of open terrain upwind of the windward forest edges. Preferential snow deposition by wind-induced snow drifting along the forest edge has been previously reported in alpine environments by Veatch et al. (2009), Essery et al. (2009), Broxton et al. (2015), and

Formatted: Heading 3, Outline numbered + Level: 3 + Numbering Style: 1, 2, 3, … + Start at: 1 + Alignment: Left + Aligned at: 0" + Indent at: 0.5"

Currier and Lundquist (2018). However, there seems to be only limited penetration of blowing snow inside the forest in windward directions (*WFE* forest points in Fig. ~~6a~~8a, b and Fig. 6d, e).

~~Forest S~~shading by the forest edge seemingly does not have a significant influence on the snow depth variability ~~in~~ at these sites during the accumulation season. Shading effects would however probably have some influence on snow depth patterns ~~in~~ during the melting season (Hojatimalekshah et al., 2021). ~~This~~ The ~~high~~ spatial heterogeneity of snow depths and associated processes challenge ~~the~~ distributed snow modeling using ~~hydraulic~~ hydrologic response units (HRUs) in agro-forested landscapes (Aygün et al., 2020), where HRUs are classified as field and forest patches but disregard boundary effects. Aygün et al., (2020) successfully modelled ~~(with a~~ Nash–Sutcliffe efficiency of 0.57 over 23-year simulation of SWE) blowing snow transport in fields and the preferential accumulation in canals and streams, and assumed that once these were filled, any further blown snow accumulated in the forest. Our results confirm the preferential accumulation in field canals and streams but suggest that further blown snow first preferentially accumulates at the forest edge, which should eventually be represented as distinct HRUs in distributed hydrological models of agro-forested landscapes.

4.3.2 At the b~~At the b~~oreal forested site

The findings in agro-forested sites are in contrast with the boreal forested environment, where forest structure (*LAI*) predominates on the variability of snow depth (Fig. ~~5~~7 and Fig. ~~6~~8). The small field appears to have fewer microtopographic features and is mostly sheltered from the most frequent winds coming from the northwest direction (Fig. 2c). The r~~R~~elatively greater positive *TWSI* values ~~in~~ at this site compared to agro-forested sites imply more rugged microtopography and a larger degree of wind sheltering in the forested terrain (Fig. 8c and Supplement Fig. S4). However, since wind is mostly impeded by the coniferous trees, the *TWSI*-snow depth relationship in the forest suggests that the snow displacement is driven by small-scale bounce/ejection/roll mechanisms, and preferential snow deposition is driven by immobilizing mechanisms such as adhesion, cohesion, and physical interlocking of snow particles (Filhol and Sturm, 2019) and unloading of snow by the canopy (Zheng et al., 2019). The lesser importance of *TWSI* (~~28 %~~0.41 compared to ~~73 %~~0.97 of *LAI*, the dominant ~~variable~~predictor, Fig. ~~5~~7) as snow depth~~a~~ predictor in the coniferous forest compared to deciduous (*TWSI* = 0.74, the dominant predictor) and mixed (*TWSI* of 0.25 compared to 0.33 of *WFE*, the dominant predictor) forests~~,~~, and the more or less constant snow depth values ~~for~~ at ~~slopes higher than 5°~~ higher *TWSI* values (Fig. ~~6c~~8c) suggest that microtopography has a more restricted influence on deeper snowpack at this site compared to the shallower snowpack at the ~~other~~ agro-forested sites. In other words, in ~~i.e., in~~ the absence of wind, increasing snow depths reduce/inhibit surface undulations and promote more spatially continuous snow cover (Filhol and Sturm, 2019). The spatial arrangement of the trees may have a larger control on snow depths in the boreal forest, i.e., forest gaps in the coniferous forest with various slopes and aspects create pronounced and distinct snow depth variabilities inside the forest (Woods et al., 2006). For instance, in Montmorency, superimposed *TWSI* and *LAI* maps (Supplement Fig. S~~3~~4) show that the high snow depth values associated with *TWSI* values ~~from~~ of 10–12 (Fig. ~~6c~~8c) are associated with a forest gap that likely prevents snow interception and accumulates more snow. ~~The counterintuitive preferential snow accumulation on southern slopes in the field at Montmorency could be due to the influence of the various~~

Formatted: Heading 3, Outline numbered + Level: 3 + Numbering Style: 1, 2, 3, … + Start at: 1 + Alignment: Left + Aligned at: 0" + Indent at: 0.5"

Formatted: Font: Italic, Complex Script Font: Italic

~~meteorological stations at the site.~~ Our results support the findings of previous studies that the snow depth distribution ~~of~~ in ~~the~~ coniferous environments is mainly governed by the canopy characteristics such as structure, distribution, and type of vegetation (Winkler et al., 2005; López-Moreno and Latron, 2008; Varhola et al., 2010a; Zheng et al., 2018; Safa et al., 2021; Koutantou et al., 2022). Our findings however show that ~~But~~ the microtopography, even under wind-sheltered conditions in the forest, still ~~explains~~ plays an important part of the spatial variability.

4.3.3 At the single-tree scale

At the single-tree scale, the variability of terrain and vegetation characteristics within single tree canopies is supressed~~lower than this scale are masked~~. Our results show that masking this intra-tree variability reduces the predictive power of RF models (lower R^2, Supplement Fig. S5), and also changes the variable importance (Supplement Fig. S6) to some ~~degree~~extent. However, even at the single-tree scale, wind-related forest edge effects and microtopography still explain a major portion of snow spatial variability ~~in~~at agro-forested sites, ~~and~~while ~~in~~ at the boreal forested site, canopy characteristics and microtopography have the highest impact (Supplement Fig. S6). The most noteworthy difference in ~~variable~~landscape ~~impact~~ influence on snow depth variability comes from the slope and ~~slope orientationsapect~~aspect, which show a ~~. They show a~~ more pronounced impact on snow depth at this scale (Supplement Fig. S7). For instance, all forested areas show clear signs of snow accumulation on northerly oriented slopes (*Aspect_SN* in Supplement Fig. S7). The i~~I~~nfluence of the various meteorological stations in the Montmorency field could be the reason for prominent preferential snow accumulation on the southern slopes ~~of~~at this site. However, this ~~infers~~analysis shows that ~~that~~ at scales larger than the scale break distances ~~in~~at these sites, large-scale topographic characteristics like slope and aspect play a more significant role in shaping snow accumulation and distribution patterns than that at smaller, intra-canopy scales. ~~(i.e., scales that capture intra-tree variability like 1.4 m).~~

4.4 Comparison of RF model performances

4.4.1 Comparison between the sites

~~While not a major focus of our study, w~~~~We believe our~~Our RF model showed variable performances, with overall ~~validation~~ OOB R^2 of 0.~~28~~30 –0.~~52~~ 66 (Fig. ~~7~~9). ~~, are in an acceptable range for the purpose of our study.~~ All sites have different climates. The higher performance at Sainte-Marthe could be due to a combination of different factors. Early ~~melt of snow~~~~snowmlets~~snowmelt due to frequent rain-on-snow events in this region (Paquotte and Baraer, 2021) and the presence of basal ice as observed in the field campaigns might have contributed to a more structured snowpack in the Sainte-Marthe forest and hence improved the prediction of snow depth compared to the other agro-forested ~~site~~Saint-Maurice site. The ~~Reasonably h~~~~H~~igh R^2 values in ~~agricultural~~ fields at ~~both agro-forested~~all sites (~~0.39~~0.78 in Sainte-Marthe, ~~and 0.45~~0.60 in Saint-Maurice, and 0.57 in Montmorency) indicate that the models captured the most relevant processes through the predictor variables considered. In contrast, Saint-Maurice forest ha~~s~~d the worst performance (0.1~~7~~0). This could be due to underlying

processes/variables not considered in our model, possibly associated with the canopy structure of the mixed forest. ~~Comparatively low R^2 in Montmorency (0.17) field must have been a result of the concentric snow accumulations patterns around the precipitation gauges and other meteorological instruments that eventually degraded the prediction power of snow depth in the RF model.~~ Moreover, the reduced sampling under coniferous trees due to limited lidar penetration could also have affected grid-scale mean snow depth and resulting relationships with landscape metrics in the Montmorency forest.

4.4.2 Comparison with previous studies

The previous studies that used RF models to estimate snow depths/SWE (Bair et al., 2018; Yang et al., 2020) were mainly focused on mountainous watersheds with large elevation gradients and with less or no vegetation and reported average Nash–Sutcliffe efficiencies as high as ~0.7 and RMSEs of 44–73 mm, where the major part of this variance was explained by elevation. Safa et al. (2021) developed site-specific RF models to predict snow-covered areas using vegetation density, average incoming shortwave, and longwave radiation, total precipitation, and average air temperature and reported mean absolute errors of 0.05–0.12 m in mixed coniferous sites. In addition, the abundance of studies that employed MLR (Jost et al., 2007; Lehning et al., 2011; Grünewald et al., 2013; Revuelto et al., 2014; Fujihara et al., 2017) and BRT (Winstral et al., 2002; Anderton et al., 2004; Molotch et al., 2005; Revuelto et al., 2014) in alpine environments with rocky outcrops and pasture or no vegetation also reported R^2 of 0.25–0.91 where a substantial portion of the snow depth variability was explained by terrain parameters, mostly elevation. However, model performances are shown to be degraded with the presence of forests. Studies conducted in forested terrain with relatively small elevation ranges reported R^2 of 0.25–0.51 by MLR (Zheng et al., 2016; Zheng et al., 2018) and BRT (Erxleben et al., 2002; Veatch et al., 2009; Baños et al., 2011). Musselman et al. (2008) proved that including detailed vegetation information like micro-scale vegetation-induced solar radiation, distance to the canopy, and tree bole could improve BRT performance to 0.68 in a forested area. Compared to previous works in forested terrain, we believe our model fits (overall R^2 of 0.30–0.66) are in a reasonable range.

4.4.3 Comparison to MLR models

~~Hence t~~The relatively good success of MLR in previous studies to study landscape control on snow accumulation is ~~thus~~ mostly attributed to elevational controls on snow accumulation, ~~i.e.~~i.e., orographic enhancement of precipitation gradient and adiabatic cooling which promotes higher snowfall fraction and reduced ablation at higher elevations. However, in low elevation landscapes, more complex relationships are expected between snow depths, vegetation, and topography, which would likely be poorly captured by linear relationships. As shown in Table 3, our RF models show a significant improvement with higher R^2 and lower RMSE values compared to MLR models at all sites. Since the MLR models at each site were developed using the same ~~variables~~predictors described in section 3.3.1., this ~~could only~~ suggests the deficiency of MLR models ~~itself~~ in capturing the underlying processes ~~in~~at these sites. Figure 8 shows that almost all variables have a nonlinear relationship with ~~the~~ snow depth, which linear models ~~were~~are unable to capture. Our RF results thus highlight the importance of considering

Formatted: Heading 3, Outline numbered + Level: 3 + Numbering Style: 1, 2, 3, … + Start at: 1 + Alignment: Left Aligned at: 0" + Indent at: 0.5"

Formatted: Superscript

this nonlinearity in statistical models, as RF notably allows capturing nonlinear relationships between snow accumulation and landscape variables, while protecting against the typical overfitting of single decision trees.

Table 3. Comparison of RF and MLR model performances of study sites

RF						
	R^2			RMSE		
	Field	Forest	Field+Forest	Field	Forest	Field+Forest
Sainte-Marthe	0.78	0.29	0.66	0.07	0.10	0.08
Saint-Maurice	0.60	0.17	0.46	0.08	0.10	0.09
Montmorency	0.57	0.29	0.30	0.18	0.27	0.26
MLR						
	R^2			RMSE		
	Field	Forest	Field+Forest	Field	Forest	Field+Forest
Sainte-Marthe	0.18	0.04	0.21	0.12	0.12	0.13
Saint-Maurice	0.32	0.08	0.17	0.10	0.10	0.11
Montmorency	0.02	0.13	0.12	0.26	0.30	0.29

~~**Comparison with previous studies**~~

~~The previous studies that used RF model to estimate snow depths/SWE (Bair et al., 2018; Yang et al., 2020) were mainly focused on mountainous watersheds with large elevation gradients and with less or no vegetation and reported average Nash-Sutcliffe efficiencies as high as ~0.7, where the major part of this variance was explained by elevation. Safa et al. (2021) developed site-specific RF models to predict snow-covered areas using vegetation density, average incoming shortwave, and longwave radiation, total precipitation, and average air temperature and reported mean absolute errors of 0.05–0.12 in mixed coniferous sites. In addition, the abundance of studies that employed MLR (Jost et al., 2007; Lehning et al., 2011; Grünewald et al., 2013; Revuelto et al., 2014; Fujihara et al., 2017) and BRT (Winstral et al., 2002; Anderton et al., 2004; Molotch et al., 2005; Revuelto et al., 2014) in alpine environments with rocky outcrops and pasture or no vegetation also reported R^2 of 0.25–0.91 where a substantial portion of the snow depth variability was explained by terrain parameters, mostly elevation. However, model performances are shown to be degraded with the presence of forests. Studies conducted in forested terrain with relatively small elevation ranges reported R^2 of 0.25–0.51 by MLR (Zheng et al., 2016; Zheng et al., 2018) and BRT (Erxleben et al., 2002; Veatch et al., 2009; Baños et al., 2011). Musselman et al. (2008) proved that including detailed vegetation information like micro-scale vegetation-induced solar radiation, distance to the canopy, and tree bole could improve BRT performance to 0.68 in a forested area. Similarly, our inclusion of small-scale vegetation characteristics and terrain variables in RF model has contributed to an improved model fit (better validation R^2) compared to previous works in forested terrain. Compared to previous works in foreted terrain, we believe our model fits (overall R^2 of 0.30–0.66) are in a reasonable range.~~

4.5 Note on potential variables/predictors in similar landscapes

One particularity of our sites (also related to the scale of the analysis) is the negligible elevation range. Many studies conducted in mountainous environments have shown the preponderant influence of elevation on the distribution of snow cover. While the elevation range becomes important over a larger extent on the Canadian shield (Montmorency-type physiography), the low elevation St. Lawrence lowlands (Sainte-Marthe and Saint-Maurice) remain mostly flat, and local topography (terrain roughness) and land cover and land use are expected to control the spatial distribution of the snow cover. As confirmed by our results, in agro-forested land covers, wind-related forest edge effects will also have a substantial impact on snow deposition, and distribution patterns.

~~4.4~~4.6 Limitations of the study

This study provides ~~an~~ insight into the scaling properties of the snowpack and the effect of different topographic, vegetation, and forest edge characteristics on snow depth variability in open versus forested areas with different canopy covers. However, there are potential limitations with some of the methods presented in this study. For instance, despite our efforts to incorporate processes/variables influencing the ~~snow~~ spatial distribution of snow depths with available data, the comparatively lower performance of RF models in Saint-Maurice and Montmorency indicates that there could still be some processes/variables that ~~we~~ were unable to accounted for (e.g., soil parameters, snowpack state, and meteorological variables). Another limitation comes from the ~~Not to forget that there is also an~~ unexplained snow depth variability that is within the UAV-lidar system detection limit. Especially in Montmorency, there were observation gaps by UAV-lidar due to the thick canopy cover that eventually affected the accuracy of snow depth and ground surfaces rasters and ~~other~~ derived landscape descriptors ~~variable raster delineations~~ (e.g., slope, LAI, etc.). ~~As well, the aggregation of high-resolution rasters to larger grid sizes for use in the RF models would have averaged some small-scale variations.~~ The dominant predictors identified in this study might also depend on the timing of the survey date (e.g., near peak snow accumulation versus early and mid-winter, or during the melt period). Hence, repeat surveys with UAV-lidar to track the temporal evolution of the snowpack would be required to fully address this question in the future. However, the analysis presented here is thought to largely reflect the typical conditions at the sites and to portray key differences between agro-forested and boreal landscapes.

5 Conclusions

In this study, including wind-related forest edge effects ~~improved the statistical prediction accuracy of snow depth spatial variability by more than 50 %~~ in agro-forested sites, ~~whereas~~and incorporating canopy characteristics ~~improved the predictive accuracy by more than 60 %~~ in the coniferous site increased the statistical prediction accuracy of snow depth spatial variability by more than 90 %. This implies the importance of including and better representing these processes in process-based models. Taken together, our results suggest that in agro-forested landscapes of the St. Lawrence valley, geomorphological assemblages

drive the differential snow accumulation between field and forested areas, i.e., rugged glacial deposits with preserved forests favor more snow accumulation whereas flat glaciomarine sediments in the exposed fields promote ~~less snow accumulation and more~~ snow erosion. The blowing snow redistributed from the fields gets trapped in canals/streams and accumulates along the forest edges, accounting for the highest local snow depths in these landscapes. ~~As well~~Furthermore, within deciduous/mixed forests, it is rather the underlying topography and/or the forest edges that govern the snow depth variability, while within the coniferous environment, it is the forest structure variability. More often, these processes are not fully represented in process-based models. For instance, most of the process-based models like CRHM (Pomeroy et al., 2007), and SnowModel (Liston and Sturm, 1998) prescribe a single, typical LAI for land cover classes. This ignores the variability within stands which could compromise larger scale estimates of snowpacks. The recent development of hyper-resolution process-based models does account for fine scale canopy structure (Mazzotti et al., 2020a; Mazzotti et al., 2020b), yet representing microtopographic characteristics like terrain roughness is still problematic. Our results suggest that snow redistribution ~~in~~ at forest edges, ~~forest structure~~ spatial variability of forest structure, and better representation of microtopography and prominent topographical features such as canals are important processes/variables that should be taken into account in process-based models. This highlights the advantage of using high resolution data to characterize small-scale processes and therefore explicitly resolve snow depth variability.

In addition, since the selected sites are representative of typical agro-forested and boreal landscapes in southern Québec, the findings of this study could be applied/extrapolated to similar landscapes in the region and any similar environments where similar processes operate. It is worth noting that future efforts in designing modeling parameterizations that include forest edge effects would benefit from incorporating the meteorological conditions together with topographic and vegetation characteristics.
