12 **Abstract.** The ice–ocean boundary layer parameters are one of the main drivers of sea ice mass balance in the Polar Regions.  
13 To investigate the oceanic contribution to the landfast ice evolution, an integrated ocean observation system, including  
14 Acoustic Doppler Velocimeter, COMPACT-CTD, and Sea Ice Mass Balance Array, was deployed near Zhongshan Station in  
15 Prydz Bay, East Antarctica. The minute-resolution of ocean temperature, salinity, density, current, and heat flux from 16 to 23  
16 April, 2021 were obtained and analysed. The results showed that ocean temperature experienced a jump increase, from -  
17  $1.59\pm 0.03^{\circ}\text{C}$  during 16–19 April to  $-1.47\pm 0.07^{\circ}\text{C}$  during 20–23 April, which may relate to the tide transform from semi-diurnal  
18 to diurnal. Ocean salinity and density showed a gradual trend increasing by  $0.013\text{ psu day}^{-1}$  and  $0.009\text{ kg m}^{-3}\text{ day}^{-1}$ , respectively,  
19 related to the salt rejection of ice bottom freezing. The mean ocean velocity was  $3.13\pm 1.63\text{ cm s}^{-1}$  and 34% of the current  
20 directions accounted to the northwest. Oceanic heat flux was estimated by the bulk parameterization method and residual  
21 energy method, which were  $32.26\pm 18.07\text{ W m}^{-2}$  and  $34.95\pm 17.52\text{ W m}^{-2}$ , averaged for the study period respectively. Oceanic  
22 heat flux showed a large increase during 20–23 April, which shut down ice growth and resulted in 2 cm melting at the ice  
23 bottom. The high frequency of ocean observations allows us to deeply investigate diurnal changes of oceanic regimes and  
24 understand their influences on sea ice evolution.

## 25 1 Introduction

26 In recent years, global warming has become more and more pronounced especially in the high latitudes (Manabe and Stouffer,  
27 1980; Screen and Simmonds, 2010; Clem et al., 2020). Notably, the Antarctic region plays a pivotal role in driving and  
28 modulating climate change on global scale (Massom and Stammerjohn, 2010). As a structural part of the polar ecosystem, sea  
29 ice conditions reflect the polar ocean conditions and play a crucial role in the marine system and ecosystem structure. In  
30 contrast to the rapid decline of Arctic sea ice since the late 1970s, Antarctic sea ice as a whole showed a slight trend of increase  
31 up to recent years (Comiso et al., 2008; Liu and Curry, 2010). Antarctic sea ice extent peaked at above  $20\times 10^6\text{ km}^2$  in 2014,

32 but since has exhibited decreasing summer minima and winter maxima (Parkinson and DiGirolamo, 2021). Antarctic sea ice  
33 extent has reached a new all-time low in 2021/22 (Raphael and Handcock, 2022; Wang et al., 2022), the causality for this  
34 remains under discussion.

35

36 Fast ice is prevalent in Antarctic coastal areas, usually attached to the shorelines, ice shelves, glacier tongues, grounded  
37 icebergs, or grounded shoals (Massom et al., 2001; Li et al., 2020). Compared with floating ice in the same region, the landfast  
38 ice has a longer annual duration and generally is thicker, and its width can extend tens to hundreds of kilometres from the  
39 shore. At the time of maximum winter sea ice extent in the Southern Hemisphere, the landfast ice area accounts for about 3–  
40 4% of the total Antarctic sea ice area (Li et al., 2020), and the volume for about 14–20% of the entire Antarctic sea ice volume  
41 (Fedotov et al., 2013). The proportion of landfast ice off East Antarctica exceeds that of other Antarctic regions (Giles et al.,  
42 2008; Li et al., 2020). As a natural barrier between the ocean and the atmosphere, landfast ice strongly influences the interaction  
43 between the air–ocean interface and the heat flux and water vapour exchange between the ocean and the atmosphere (Maykut  
44 and Untersteiner, 1971; Heil et al., 1996; Heil, 2006). The formation of landfast ice mainly depends on the thermodynamic sea  
45 ice growth. The existence and growth of landfast ice provide some of the essential functions for the Antarctic environment  
46 such as providing a barrier to the glacial ice sheet (Massom and Stammerjohn, 2010; Miles et al., 2017) that otherwise would  
47 be less constrained to calve and vanish into the Southern Ocean. Therefore, landfast ice is a crucial component in the Earth  
48 system that cannot be ignored when assessing the role of Antarctica in the global climate system. Oceanic heat flux plays a  
49 critical role in thermodynamic models of sea ice growth and is a crucial factor affecting the mass balance of sea ice. Parkinson  
50 and Washington (1979) confirmed that seasonally varying oceanic heat flux impacts the annual sea ice growth. Understanding  
51 changes in oceanic heat flux under ice plays a vital role in determining ice thickness and seasonal sea ice variations.

52

53 Oceanic heat flux can be estimated by measuring the temperature gradient, growth rate, and sea ice salinity (McPhee and  
54 Untersteiner, 1982). Allison (1981) studied the landfast ice around Australia's Antarctica Mawson Station and found that the  
55 oceanic heat flux showed a maximum value at the beginning of the sea ice growing season because the rapid growth of sea ice  
56 established thermohaline convection and deepened the mixing layer by pumping warm water up. Heil et al. (1996) estimated  
57 that mean annual oceanic heat flux at Australia's Antarctica Mawson Station ranged from 5 to 12 W m<sup>-2</sup>. Lei et al. (2010)  
58 studied the interannual variation of landfast ice in Prydz Bay during 2006 and pointed out that in the early stage of sea ice  
59 growth, both the vertical temperature gradient of thin ice and the ice growth rate fluctuate strongly. Oceanic heat flux  
60 estimations based on the flux balance equation at the ice–ocean interface varies from 7 to 18 W m<sup>-2</sup> (based on 8 psu salinity),  
61 with an oceanic heat flux of 11.8±3.5 W m<sup>-2</sup> in April. Yang et al. (2016) calculated the oceanic heat flux in Prydz Bay by using  
62 the HIGHTSI model with sea ice thickness measurements as input parameters. During the sea ice growing season (March–  
63 November), the mean oceanic heat flux was 10 W m<sup>-2</sup> and gradually decreased from the highest 25 W m<sup>-2</sup> to 5 W m<sup>-2</sup>. Zhao et  
64 al. (2019) estimated the oceanic heat flux beneath sea ice in Prydz Bay using the residual energy method and found that the  
65 oceanic heat flux ranged from 20.0 to 40.0 W m<sup>-2</sup> during the early growth of landfast ice in Prydz Bay in 2011. In March, the

66 maximum monthly mean value was  $33.8 \pm 7.5 \text{ W m}^{-2}$ . While previous studies focused on seasonal variation and interannual  
67 circulation of oceanic heat flux, there are few studies on short-term transient changes of oceanic heat flux in the early stage of  
68 sea ice growth. McPhee et al. (1996) found that oceanic heat flux also changed significantly on the sub-diurnal scale with the  
69 continuous flow of subglacial cold and warm ocean currents. Therefore, studying the effects of oceanic heat flux changes on  
70 sea ice growth at the sub-diurnal scale is important.

71  
72 Our study investigates the minute-resolution changes of oceanic heat flux beneath sea ice during the early growth season near  
73 Zhongshan Station in Prydz Bay, East Antarctica. The motivation is to understand how oceanic heat flux affects the sea ice  
74 growth in a diurnal scale, and to study the relationship between ocean temperature and current direction and their influence on  
75 oceanic heat flux. We estimated oceanic heat flux using two different methods: (a) residual energy method based on modified  
76 Stefan's Law; (b) a holistic parameterization approach using frictional velocities and the available heat content of frozen water.  
77 Based on ocean temperature, salinity, and velocity observed by ADV, CTD, and SIMBA, the high time resolution changes of  
78 oceanic heat flux were calculated and compared with previous studies. Section 2 describes field observations used in this study.  
79 The results, including ocean temperature, salinity, density, and oceanic heat flux estimation are presented in Sect. 3. The  
80 discussion is in Sect. 4, and conclusions are provided in Sect. 5.

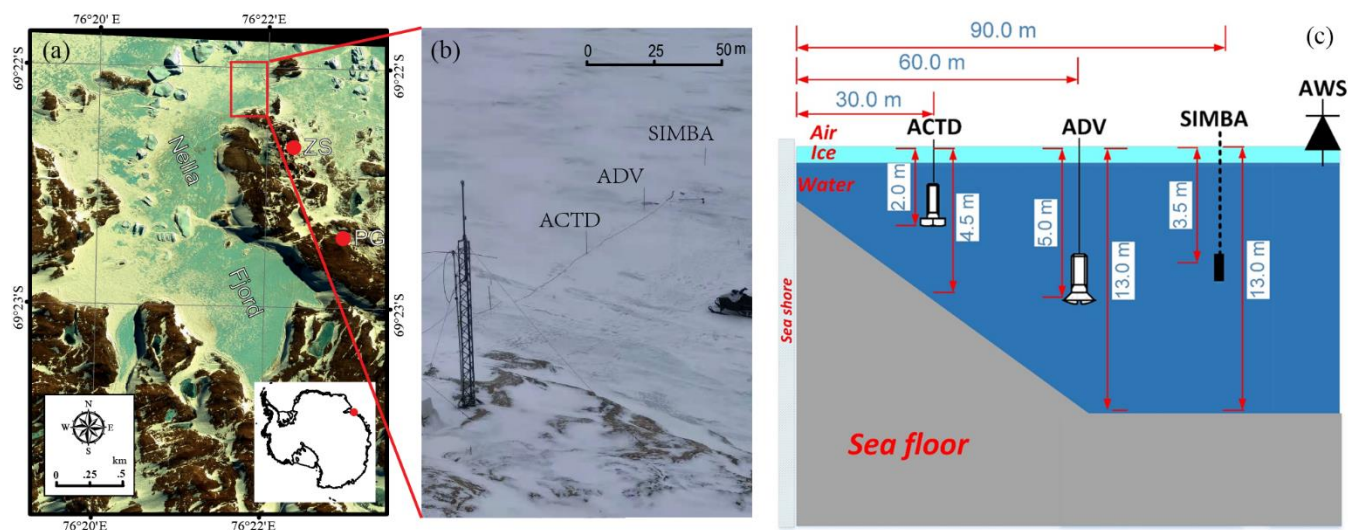

## 81 **2 Observations**

82 Zhongshan Station ( $69^{\circ}22' \text{ S}$ ,  $76^{\circ}22' \text{ E}$ ), the second Chinese Antarctic scientific research station, was established in February  
83 1989 and operated year-round from then on. It is located in Prydz Bay, East Antarctica (Fig. 1a), and the surrounding near-  
84 coastal ocean is covered by landfast ice from February to December. In the cold season, the extent of landfast ice may reach  
85 up to 60–100 km north of Zhongshan Station. Typically, late every austral summer (i.e., late January), the landfast ice breaks  
86 up due the mechanical forcing provided by wind stress, waves, and tide. The sea ice cover is then completely removed, with  
87 exception of some small ice floes that may survive in narrow fjords and become second or multi-year sea ice in the subsequent  
88 winter.

89  
90 During 16 to 23 April 2021, an integrated ice–ocean interaction observation system was set up by the wintering team in the  
91 coastal landfast ice about 1 km off Zhongshan Station (Fig. 1b). A cable-type CTD (model: ALEC ACTD-DF) was deployed  
92 at 2 m beneath the ice surface and 30 m off the shoreline, where the water depth was 4.5 m. The measurement frequency was  
93 both 30 s for the conductivity and temperature sensors. The accuracy was  $\pm 0.02 \text{ mS cm}^{-1}$  ( $\pm 0.03 \text{ psu}$ ) for conductivity (salinity)  
94 and  $\pm 0.02^{\circ}\text{C}$  for temperature. An Acoustic Doppler Velocimeter (model: SonTek Argonaut-ADV) was deployed 30 m north  
95 of ACTD 5 m below the ice surface, where the water depth was 13.0 m. The frequency for velocity observations was 40 s, and  
96 the sensor accuracy was  $\pm 0.001 \text{ m s}^{-1}$ . A Sea Ice Mass Balance Array (model: SRSL SIMBA) was deployed 30 m north of  
97 ADV, where the water depth was also 13.0 m. The SIMBA contained 240 temperature sensors mounted on the thermistor

98 string with 2 cm intervals to measure the vertical temperature profile across the air–snow–ice–ocean column every six hours,  
99 at an accuracy of  $\pm 0.0625^{\circ}\text{C}$  (Fig. 1c).  
100  
101 Snow depth and ice thickness were measured manually every five days around the integrated ice–ocean interaction observation  
102 system. The records showed that snow and ice thickness was 0.045 m and 0.440 m on 16 April, while 0.020 m and 0.460 m  
103 on 21 April 2021.

104

## 109 3 Results

### 110 3.1 Ice evolution

111 The SIMBA temperature chains record the vertical temperature profiles at the atmosphere–ocean interface through the  
112 atmosphere–snow–sea ice–ocean column. Numbering of thermistors starts at lowest of the temperature chain (in ocean). Figure  
113 2a and 2b respectively show the vertical temperature profile and vertical temperature gradient of temperature data recorded by  
114 the temperature chain. This is evident from Fig. 2a, the daily variation in air temperature (sensors 180–200) was significant,  
115 with a maximum of  $4.24^{\circ}\text{C}$  between two adjacent days (in austral winter), and the air temperature was much lower than the  
116 ice and ocean temperature during the study period. The sea ice temperature (sensor 155–180) showed a significant gradient,  
117 varied between  $0.11^{\circ}\text{C cm}^{-1}$  and  $0.24^{\circ}\text{C cm}^{-1}$ . The ocean temperature (sensor 0–155) is maintained between  $-1.7^{\circ}\text{C}$  and  $-1.9^{\circ}\text{C}$ ,  
118 close to the freezing point. The difference in thermal conductivity between air, sea ice, and ocean results in distinct vertical  
119 temperature gradients. The white dotted line showed the sea ice surface. The asterisk white solid line was the ice–water

120 interface which was determined by freezing point temperature as the threshold value. During the growth season, the ocean  
121 temperature usually remains at freezing point, which is the reason for distinguishing sea ice with a large vertical gradient from  
122 ocean with a basically constant temperature. It could be seen that the thickness of landfast ice showed an increase of about 2  
123 cm from 16 to 21 April, consistent with the increase of landfast ice thickness from 0.44 to 0.46 m observed in the field.  
124 However, after the 21 April, there was a decrease in the thickness of the landfast ice, with basal melt accounting for nearly 2  
125 cm. The basal ice loss is likely in consequence of warming of the near-surface ocean due to increased oceanic heat flux at the  
126 ice–water interface (detailed discussed later in Sect. 4.1).

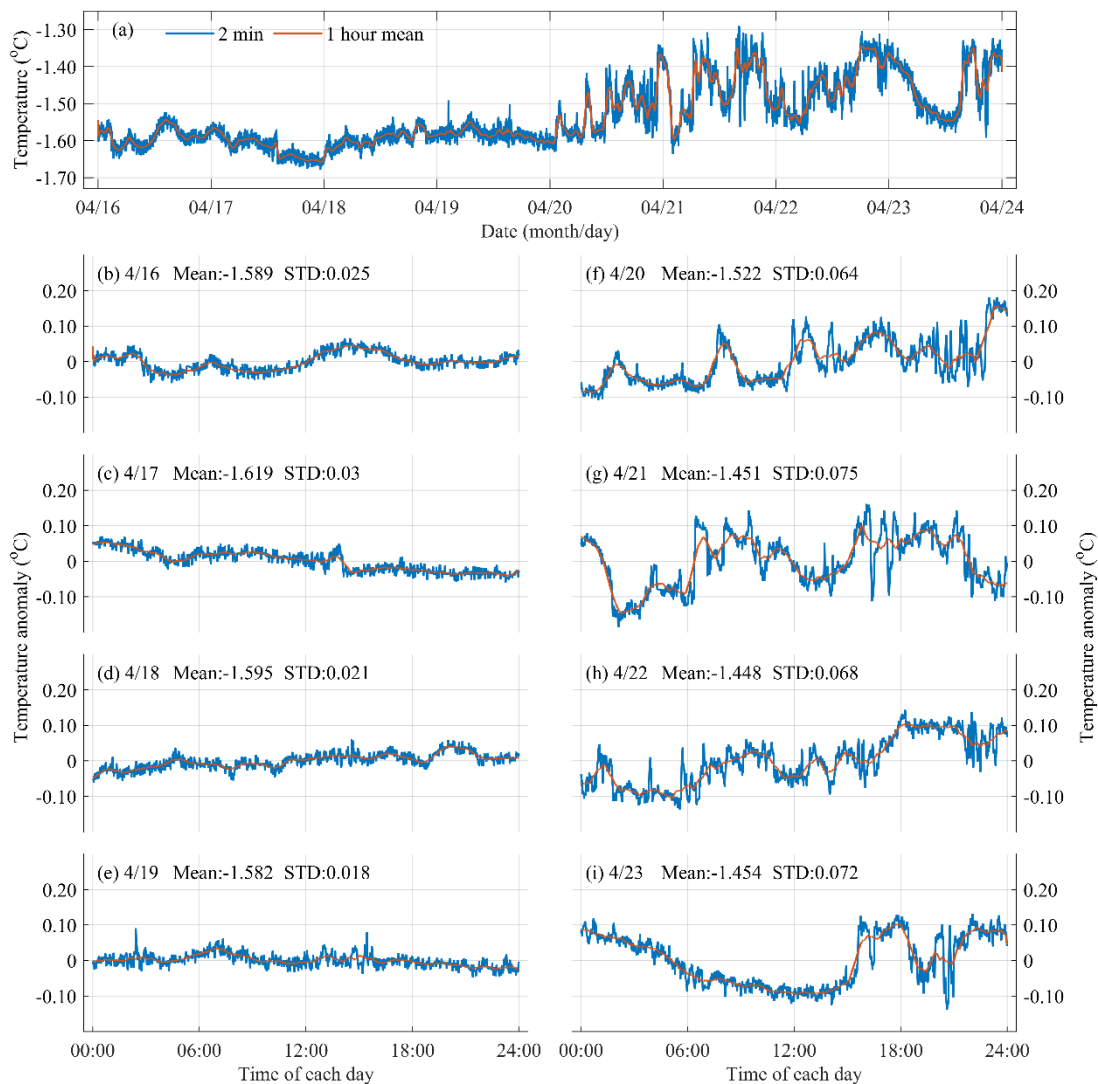

127  
128 **Figure 2. (a) Vertical temperature profiles; (b) Vertical temperature gradient. The asterisk white solid line and white dotted line in**  
129 **(a) and (b) are the ice bottom and ice surface, respectively.**

### 130 3.2 Ocean temperature

131 The ocean temperature and salinity data were obtained from ACTD deployed approximately 2 m below the landfast ice surface.  
132 The ACTD sampling rate was 30 s and recorded high-frequency temperature changes. During the study period, the ocean  
133 beneath ice was relatively warm, with an average temperature of about  $-1.53 \pm 0.08^\circ\text{C}$ , while the average temperature at the  
134 bottom of the sea ice (about 0.1 m above ice bottom) was about  $-3.12 \pm 0.71^\circ\text{C}$ . As a result, the heat transferred from warm  
135 water to cold sea ice inhibited ice bottom growth, and counteracted to the effect of the cold atmosphere on the ice surface. The  
136 ocean temperature exhibited a jump increase after 20 April (Fig. 3). The ocean temperature from 16 to 19 April remained  
137 relatively stable, with an average temperature of  $-1.59 \pm 0.03^\circ\text{C}$ , while increased significantly from 20 to 23 April, with an

138 average temperature of  $-1.47 \pm 0.07^\circ\text{C}$ . The ocean temperature showed an obvious diurnal signal, the largest daily deviation  
139 was  $0.35^\circ\text{C}$  on 21 April and the smallest one was  $0.12^\circ\text{C}$  on 18 April. Warmer temperatures allowed more heat flux to be  
140 transferred from the water to the sea ice base, balancing the conductive heat flux and inhibiting sea ice growth, consistent with  
141 the ice basal melt of 2 cm observed by SIMBA (Sect. 3.1).

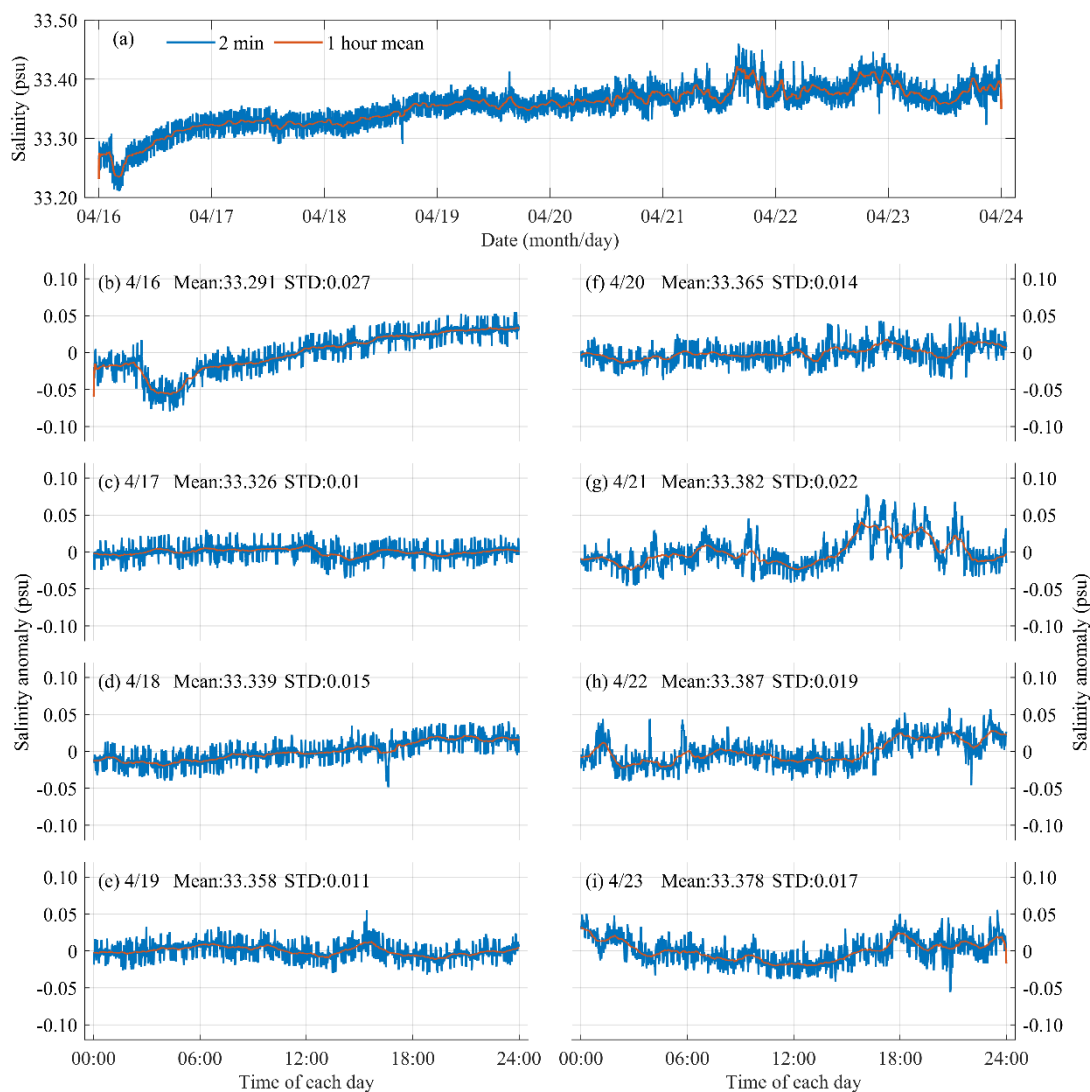

142  
143 **Figure 3. (a) The ocean temperature observed by ACTD at 2 m beneath the landfast ice surface from 16 to 23 April. (b–i) The diurnal**  
144 **anomalies based on the according daily mean. The blue and red lines represented the 2 minutes and 1 hour interval data records,**  
145 **respectively.**

### 146 3.3 Ocean salinity

147 Compared with the change of ocean temperature, ocean salinity was relative stable (Fig. 4). The largest daily deviation was  
148 0.14 psu on 16 April and the smallest was 0.66 psu on 17 April. During the study, the ocean salinity remained at  $33.35 \pm 0.03$   
149 psu, and the mean upward trend was fast ( $0.017 \text{ psu day}^{-1}$ ) during 16 to 19 April and then slow ( $0.003 \text{ psu day}^{-1}$ ) from 20 to  
150 23 April, which might be related to the slowdown of the growth of sea ice in the following days due to the increase of the  
151 ocean temperature. The temperature rise shut down the ice bottom freezing, then slowed down the salt rejection of sea ice.

152

153 **Figure 4.** (a) The ocean salinity observed by ACTD at 2 m beneath the landfast ice surface from 16 to 23 April. (b–i) represent the  
154 diurnal anomalies based on the according daily mean. The blue and red lines represented the 2 minutes and 1 hour interval data  
155 records, respectively.

### 156 3.4 Ocean density

157 The ocean density is a function of temperature and salinity. Millero and Poisson (1981) proposed an internationally recognized  
158 atmospheric equation for the state of ocean, which is calculated as follows:

$$159 \quad \rho - \rho_0 = AS + BS^{3/2} + CS^2 \quad (1)$$

160 Where,  $\rho$  and  $\rho_0$  are functions of temperature ( $^{\circ}\text{C}$ ) and salinity, the coefficients for the combined data are:

$$161 \quad A = 8.24493 \times 10^{-1} - 4.0899 \times 10^{-3}t + 7.6438 \times 10^{-5}t^2 - 8.2467 \times 10^{-7}t^3 + 5.3875 \times 10^{-9}t^4 \quad (2)$$

$$162 \quad B = -5.72466 \times 10^{-3} + 1.0227 \times 10^{-4}t - 1.6546 \times 10^{-6}t^2 \quad (3)$$

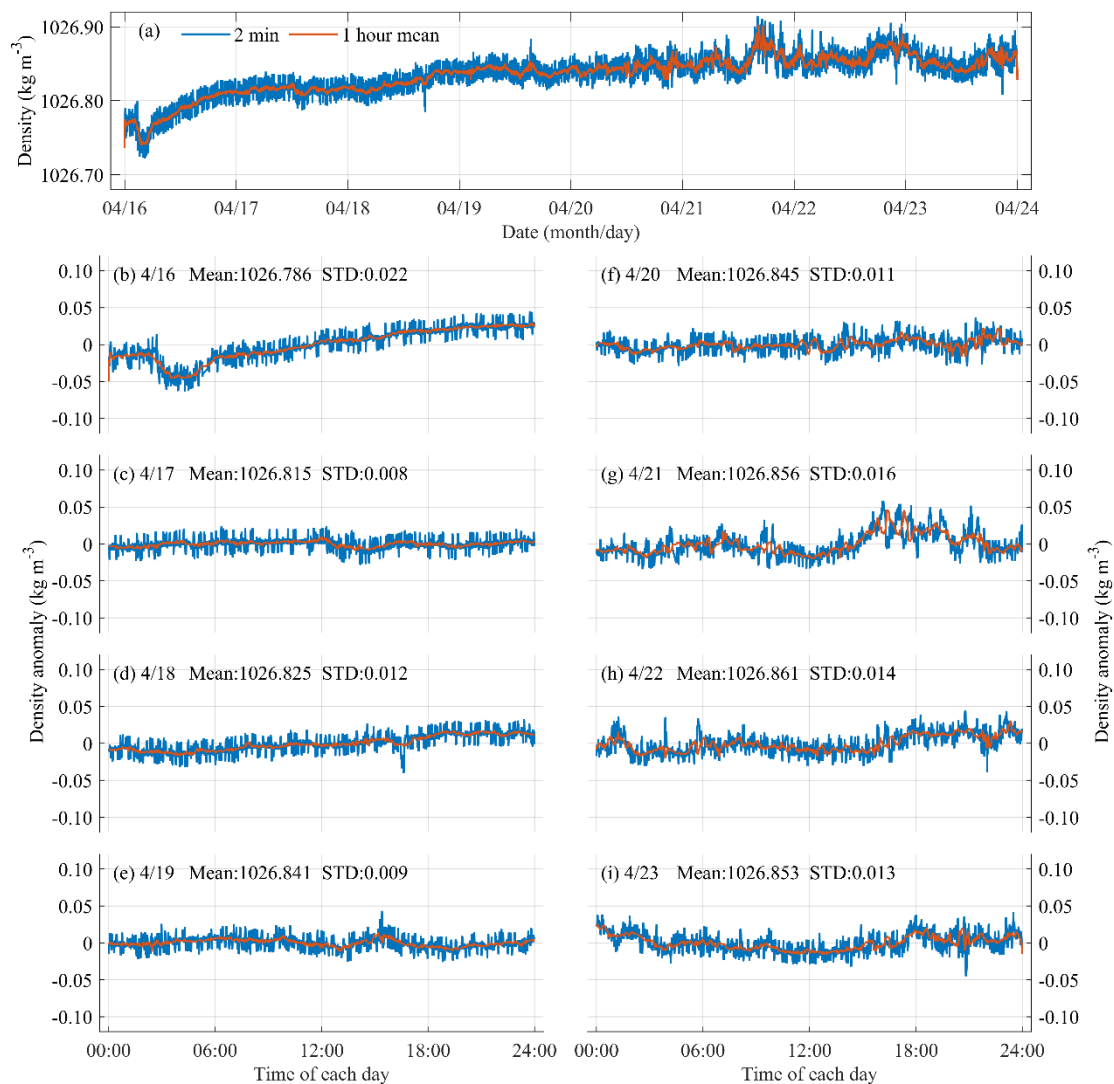

$$163 \quad C = 4.8314 \times 10^{-4} \quad (4)$$

164 The absolute densities could be calculated using the value for pure water from (Bigg, 1967):

$$165 \quad \rho_0(\text{kg} \cdot \text{m}^{-3}) = 999.842594 + 6.793952 \times 10^{-2}t - 9.095290 \times 10^{-3}t^2 + 1.001685 \times 10^{-4}t^3 \\ 166 \quad -1.120083 \times 10^{-6}t^4 + 6.536332 \times 10^{-9}t^5 \quad (5)$$

167 Combining the salinity equation above with the ocean temperature and salinity measured by ACTD, it is convenient to calculate  
168 the change of ocean density under landfast ice. The ocean density exhibits an overall increasing trend during the study from  
169 16 to 23 April (Fig. 5). During the study, the average density of the mixed layer was  $1026.84 \pm 0.02 \text{ kg m}^{-3}$ , and the mean  
170 increasing trend was fast ( $0.011 \text{ kg m}^{-3} \text{ day}^{-1}$ ) during 16 to 19 April with an average density of  $1026.82 \pm 0.02 \text{ kg m}^{-3}$ , and then  
171 slow ( $0.003 \text{ kg m}^{-3} \text{ day}^{-1}$ ) from 20 to 23 April, but the daily density variation was also severe, with an average density of  
172  $1026.86 \pm 0.01 \text{ kg m}^{-3}$ . The largest daily deviation was  $0.11 \text{ kg m}^{-3}$  on 16 April and the smallest one was  $0.05 \text{ kg m}^{-3}$  on 17  
173 April.

174

175 **Figure 5. (a) The ocean density calculated by the temperature and salinity observed by ACTD at 2 m beneath the landfast ice surface**  
176 **from 16 to 23 April. (b–i) represent the diurnal anomalies based on the according daily mean. The blue and red lines represented**  
177 **the 2 minutes and 1 hour interval data records, respectively.**

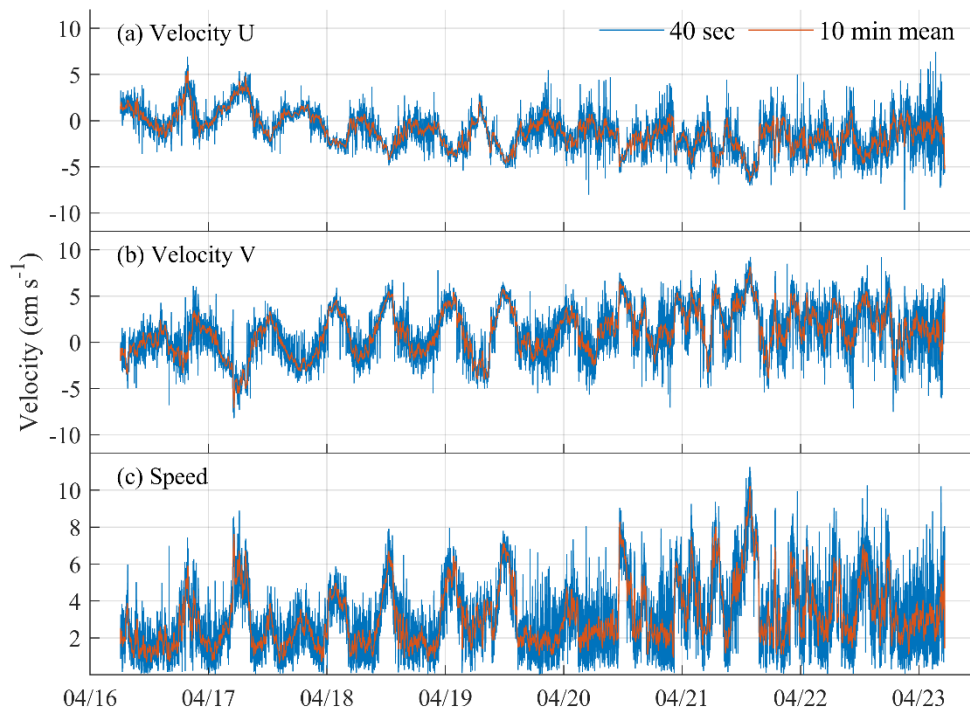

### 178 3.5 Ocean current

179 The current velocity beneath the landfast ice was obtained from ADV about 5 m below the ice surface. Figure 6 showed the  
180 velocity of due north (V), due east (U), and the vector sum of U and V. It can be seen from the figure that, the current velocity  
181 was relatively stable and showed periodic oscillation, with an average speed of about  $3 \text{ cm s}^{-1}$  and a maximum of about  $10 \text{ cm}$   
182  $\text{s}^{-1}$ . Combined with the ROSE analysis of the current direction (Fig. 7), the domain direction of the current outside Zhongshan  
183 Station is mainly northwest ( $300^\circ\text{--}330^\circ$ ).

184

185 The daily ocean current direction showed a periodic change under the influence of the tide. In general, the current in this area  
186 was mainly compound current and northwest offshore current. Fig. 8 showed the daily current and water level anomaly from  
187 16 to 23 April. The water level anomaly for Zhongshan Station was obtained from the Bureau of Meteorology, Australia. The  
188 direction of the ocean current around Zhongshan station was alternating under the action of tide, mainly the offshore current  
189 in the northwest direction ( $315^\circ$ ). From 16 to 19 April, the ocean current indicated a semi-diurnal tides condition. From 9:00  
190 to 15:00 and from 21:00 to 3:00 of the next day, it was mainly the offshore flow in the northwest direction ( $315^\circ$ ), along with  
191 the water level anomaly gradually decreased. From 3:00 to 9:00 and from 15:00 to 21:00, it was mainly the onshore flow in  
192 the southeast direction ( $135^\circ$ ), and the water level anomaly increased gradually. However, from 20 to 23 April, the onshore  
193 flow gradually decreased, and the offshore flow gradually increased, indicated a change from semi-diurnal tide to full diurnal  
194 tide. The change of tide condition weakened the vertical mixing, led to relative warm water existing under the landfast ice, and  
195 then affected the oceanic heat flux (detailed discussed later in Sect. 4.1).

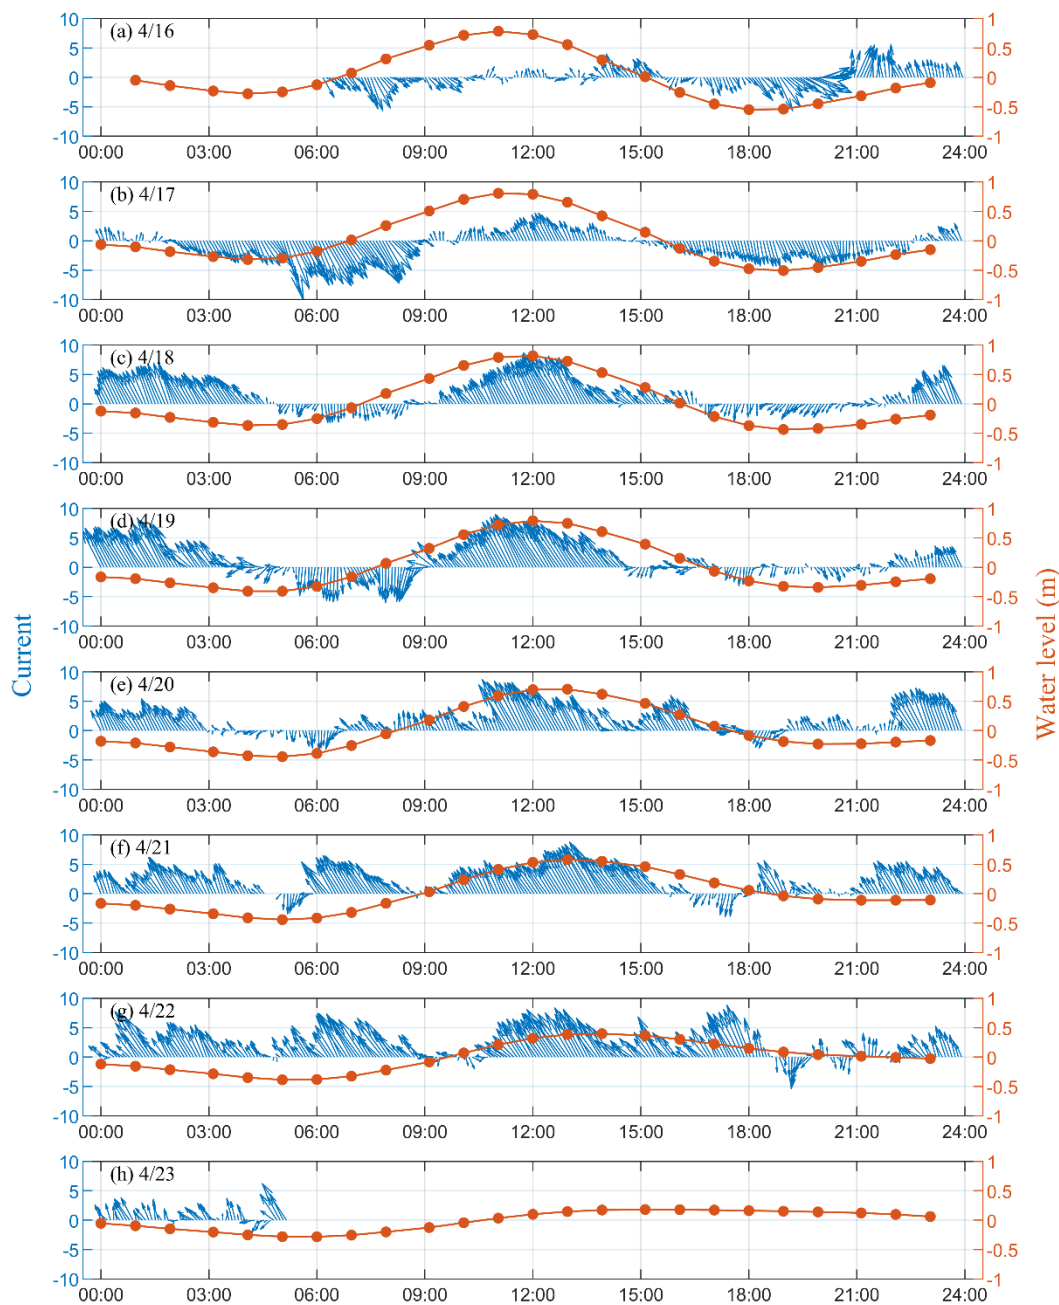

196

202 **the 2 min direction and velocity of the ocean current observed by ADV; the solid red line indicates the hourly water level anomaly**  
203 **obtained from BoM, Australia.**

## 204 3.6 Oceanic heat flux

### 205 3.6.1 Residual energy method

206 The heat balance between ocean and atmosphere influenced the growth and melting of sea ice. During this study, mean air  
207 temperature from 16 to 23 April was about  $-10^{\circ}\text{C}$ , which provided a large upward conductive heat flux and contributed to the  
208 ice bottom growth. At the same time, the relative warmer ocean (mean  $-1.53\pm 0.08^{\circ}\text{C}$ ) provided an upward heat flux to sea ice  
209 and slowed down the bottom freezing processes. Determining the heat balance between atmosphere–ice–ocean is critical for  
210 studying sea ice mass balance. At the bottom of the sea ice, the heat balance could be expressed by an equilibrium equation as  
211 follow, and this equation could be used to estimate the residual oceanic heat flux (McPhee and Untersteiner, 1982; Perovich  
212 and Elder, 2002; Lei et al., 2014):

$$213 \quad F_w = F_c + F_l + F_s \quad (6)$$

214 Where  $F_w$  is the heat flux from the ocean to the sea ice,  $F_c$  is the heat conduction flux in the sea ice,  $F_l$  is the latent heat flux  
215 caused by the freezing or melting of the sea ice, and  $F_s$  is the specific heat flux generated by the temperature change in the ice.  
216 In the formula, the signs of melting, heating, and upward heat flow are positive, while the signs of cooling, freezing, and  
217 downward heat flow are negative.

218

219 The following equation solved the conductive heat flux:

$$220 \quad F_c = k_i \frac{T_0 - T_f}{H} \quad (7)$$

221 Where  $k_i$  is the thermal conductivity of sea ice, which is a function of temperature and ice salinity (Untersteiner, 1961);  $T_0$  is  
222 sea ice temperature at the reference layer;  $H$  is sea ice thickness;  $T_f$  is the freezing point temperature of ocean, which is a  
223 function of salinity (Millero, 1978). The freezing point temperature was estimated as:

$$224 \quad -T_f = 0.0575S_w - 1.710523 \times 10^{-3}S_w^{3/2} + 2.154996 \times 10^{-4}S_w^2 \quad (8)$$

225 Where  $S_w$  is the salinity of mixed layer water, the calculation of latent heat flux and specific heat flux could be solved by the  
226 following equation (Semtner, 1976; Lei et al., 2014):

$$227 \quad F_l = -\rho_i L_i \frac{dH}{dt} \quad (9)$$

$$228 \quad F_s = \rho_i c_i \Delta H \frac{dT}{dt} \quad (10)$$

229 Where  $\rho_i$  is the density of the bottom sea ice;  $L_i$  is the latent heat of freezing sea ice;  $c_i$  is the specific heat capacity of sea ice;  
230  $dH$  is the sea ice thickness of the reference layer;  $dH/dt$  is the growth rate of sea ice;  $dT/dt$  is the temporal gradient of reference  
231 sea ice temperature; Where  $L_f$  and  $c_i$  are functions of sea ice salinity and temperature. Lei et al. (2010) pointed out that the  
232 average annual density of landfast ice in Prydz Bay is  $910 \text{ kg m}^{-3}$ , and the density of ice under ocean ranges from 893 to 948  
233  $\text{kg m}^{-3}$ , and the average annual salinity is 4 psu. Considering that the research period of this study was the early growth of  
234 landfast ice and the high salinity in ice, the landfast ice density adopted in this study was  $940 \text{ kg m}^{-3}$ , and the saltiness was 5

235 psu. So, the following formula could be used to calculate the thermal conductivity, latent and specific heat of sea ice at different  
236 temperatures (Untersteiner, 1961; McPhee and Untersteiner, 1982; Lei et al., 2010):

$$237 \quad k_i = k_0 + 0.13 \frac{S_i}{T_i} \quad (11)$$

$$238 \quad L_i = \left[ 1 - S_i - \frac{S_i}{S_w} (1 - S_w) \right] L_f \quad (12)$$

$$239 \quad c_s = -\frac{S_i \alpha T_i^2}{L_i} + \frac{S_i}{\alpha T_i} (c_w - c_{pi}) + c_{pi} \quad (13)$$

240 Where  $k_0$  thermal conductivity of sea ice ( $2.03 \text{ W m}^{-1} \text{ }^\circ\text{C}^{-1}$ );  $S_i$  is the salinity of sea ice;  $S_w$  is mixed layer salinity;  $L_f$  is the  
241 latent heat of pure ice ( $333.4 \text{ kJ kg}^{-1}$ );  $T_i$  is the reference sea ice temperature;  $c_w$  is the specific heat capacity of water ( $4.23 \text{ kJ}$   
242  $\text{kg}^{-1} \text{ }^\circ\text{C}^{-1}$ );  $c_{pi}$  is the specific heat capacity of pure ice ( $2.01 \text{ kJ kg}^{-1} \text{ }^\circ\text{C}^{-1}$ );  $\alpha = -0.0182 \text{ }^\circ\text{C}^{-1}$  is a constant of ice salinity.

243  
244 Generally speaking, the temperature of the sea ice varies significantly due to atmospheric and ocean temperature, and the  
245 vertical temperature profile of sea ice was approximately linear in the cold season. Therefore, an appropriate reference layer  
246 was used to calculate the vertical temperature gradient in Eq. (7). Usually, previous studies selected a certain distance from  
247 the ice bottom as the reference level. McPhee and Untersteiner (1982) set the reference level of 0.50–0.90 m thick ice to 0.50  
248 m away from the ice surface. Perovich and Elder (2002) developed the reference level of ice with a thickness of 2.13–2.58 m  
249 at 1.75 m away from the ice surface. Lei et al. (2014) set the reference layer at 0.40–0.70 m above the ice base. Ice thickness  
250 in this study was around 0.4 m, 0.2 m above the ice bottom was taken as the reference level in this study, and the vertical  
251 temperature gradient in  $F_c$  was calculated by the temperatures at 0.2 m and the ice bottom.  $F_s$  represents the temporal change  
252 of heat content in sea ice inside this reference layer, and  $F_l$  is the growth or melting of the sea ice bottom.

253  
254 During the study period, the freezing point temperature estimated by Eq. (8) gradually decreased and reached the lowest value  
255  $-1.83 \text{ }^\circ\text{C}$  on 21 April, along with the evolution of ocean salinity beneath sea ice. Figure 9 shows the heat fluxes in the energy  
256 balance equation. During the study period, air temperature showed a diurnal cycle and inflected by a warm event (Fig. 2a).  
257 The conductive heat flux ( $F_c$ ) showed a response to the air temperature variation and had a certain lag.

258  
259 The variation of the latent heat flux ( $F_l$ ) was strongly correlated with the growth and ablation of sea ice. From 16 to 20 April,  
260 sea ice bottom was freezing,  $F_l$  was positive. From 21 to 24 April, due to the influence of warm and robust ocean current, a  
261 small amount of melting occurred at the ice bottom and  $F_l$  was negative.  $F_s$  was relative smaller throughout the investigation  
262 period, varying around 0. The estimated 6 hour oceanic heat flux showed a significant increase before 21 April and then decline.  
263 The average oceanic heat flux was  $23.40 \pm 5.35 \text{ W m}^{-2}$  during 16–19 April, and  $45.06 \pm 18.30 \text{ W m}^{-2}$  during 20–23 April. The  
264 average of oceanic heat flux during the whole study period was  $34.95 \pm 17.52 \text{ W m}^{-2}$ . The average daily oceanic heat flux  
265 reached the maximum  $66.51 \pm 2.96 \text{ W m}^{-2}$  on 21 April, according to a bottom melting (about 2 cm) at the bottom of sea ice.

### 269 3.6.2 Bulk parameterization method

270 This section will consider measurements of current, temperature, and salinity in the upper ocean mixed layer beneath ice cover  
 271 to evaluate the turbulent heat flux at the ice–ocean interface by the parameterized method.

272

273 Sea ice provides a rigid constraint on heat flow in the upper ocean boundary layer at the ice–ocean interface, where the  
 274 temperature is close to freezing point in the growth season. The heat flux  $F_w$  from the mixed layer at the bottom of the sea ice  
 275 could be calculated by the following formula (Guo et al., 2015):

$$276 F_w = \rho_w c_w \langle w'T' \rangle \quad (14)$$

277 Where  $\rho_w$  is the density of the ocean in the mixed layer,  $c_w$  is the specific heat capacity of ocean (3980 kJ kg<sup>-1</sup> °C<sup>-1</sup>);  $\langle w'T' \rangle$  is  
 278 the turbulent heat flux. The heat transfer from the mixed layer to the sea ice depends on both the turbulent stress at the ice–  
 279 ocean interface (characterized by frictional velocity  $u_0^*$  as the square root of the kinetic stress at the interface) and the effective  
 280 heat content of the fluid in the turbulent boundary layer, which is roughly proportional to the height of the mixing layer  
 281 temperature above freezing point (McPhee, 1992; MCPhee et al., 1999; Kirillov et al., 2015). The turbulent heat flux could be  
 282 parameterized as:

$$283 \langle w'T' \rangle = c_H u_0^* \Delta T \quad (15)$$

284 Where  $c_H$  represents the Stanton number of heat exchange efficiency, is the difference between the mixed layer temperature  
 285 and its freezing point temperature,  $u_0^*$  is the friction velocity at the interface. For the bottom boundary layer of sea ice, the  
 286 exchange coefficient has been shown to be almost constant,  $c_H = 0.0057$  (McPhee, 2002). Therefore, Eq. (14) could be  
 287 expressed as:

288 
$$F_w = \rho_w c_w c_H u_0^* \Delta T \quad (16)$$

289 Due to the lack of a velocity profile or roughness of the bottom boundary layer of sea ice, it is usually assumed by the law of  
290 quadratic resistance to be related to free-stream current beyond the boundary layer, i.e., the friction velocity uses a statistical  
291 relationship to determine  $u_0^*$  from the square root of the kinematic ice–ocean stress ( $\tau$ ) (McPhee, 1979):

292 
$$u_0^2 = \sqrt{\tau} \quad (17)$$

293 
$$\tau = 0.0104V^{1.78} \quad (18)$$

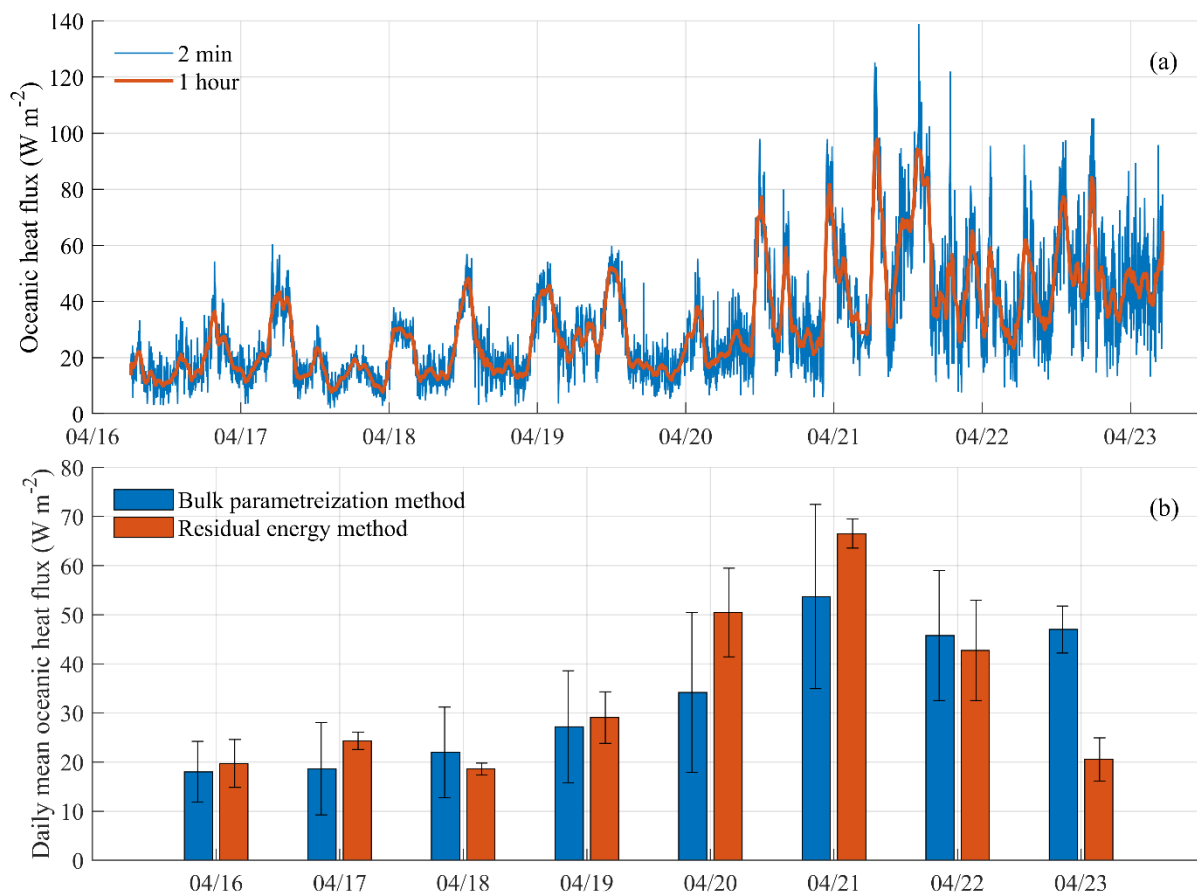

294 Where,  $V$  is absolute flow velocity relative to stationary landfast ice, recorded from ADV (about 5 m below the ice surface).  
295 During the study period, the freezing point temperature of ocean decreased gradually along the increase of ocean salinity, and  
296 the height of ocean temperature higher than freezing point ( $\Delta T$ ) increased gradually, with a mean of  $0.29 \pm 0.08^\circ\text{C}$ . From 16 to  
297 19 April, the average  $\Delta T$  was  $0.27 \pm 0.02^\circ\text{C}$ . With the jump increase of ocean temperature, the average  $\Delta T$  increased to  $0.36 \pm 0.07^\circ\text{C}$   
298 during 20–23 April.

299  
300 The daily range of oceanic heat flux calculated was  $18.02\text{--}53.70 \text{ W m}^{-2}$  for bulk parameterization method, and  $19.72\text{--}66.51$   
301  $\text{W m}^{-2}$  for the residual energy method (Fig. 10a). According to bulk parameterization method, mean oceanic heat flux was  
302  $32.26 \pm 18.07 \text{ W m}^{-2}$  from 16 to 23 April, of which it was  $21.71 \pm 10.08 \text{ W m}^{-2}$  from 16 to 19 April, and was  $44.64 \pm 17.50 \text{ W m}^{-2}$   
303 from 20 to 23 April. The detailed were shown in the Table 1.

304  
305 According to the average daily oceanic heat flux calculated by the two methods shown in Fig. 10b, it can be seen that the two  
306 methods produced similar diurnal variations of oceanic heat flux during the study period, which were relatively small before  
307 April 20 and increased significantly thereafter. However, the variance of daily oceanic heat flux was significantly different  
308 between the two methods. Compared with the residual energy method, the daily variance of bulk parameterization method was  
309 larger, which could reflect the instantaneous change of oceanic heat flux due to the observation data with high sampling  
310 frequency.

311  
312 The results of oceanic heat flux indicated that the significant increase of ocean temperature in the mixed layer beneath the  
313 landfast ice on 20 April caused a significant increase of oceanic heat flux. A large amount of heat was transferred to the sea  
314 ice through ocean since 21 April, contributed to the basal sea ice melt (about 2 cm) observed by SIMBA. The minute-resolution  
315 observations of ocean temperature, salinity, density, and velocity beneath landfast ice measured by ADV and ACTD provided  
316 a good chance to investigate the rapid and detailed changes of oceanic heat flux, which effectively impact the growth of sea  
317 ice.

318

 320 **min and 1 hour results, respectively; (b) Daily mean oceanic heat flux calculated by two different methods: Bulk parameterization**  
 321 **method and Residual energy method.**

322 **Table 1. Inter-comparisons of mean oceanic heat flux of two methods for calculating oceanic heat flux (W m<sup>-2</sup>)**

Methods	16–19 April	20–23 April	Totally
Residual energy method	23.40±5.35	45.06±18.30	34.95±17.52
Bulk parameterization method	21.71±10.08	44.64±17.50	32.26±18.07

## 323 4. Discussions

### 324 4.1 The potential influences of tide on oceanic heat flux

325 The current observations from ADV indicated a diurnal back and forth movements under the landfast ice in the influences of  
326 tides, and further analysis suggested a dominated direction of northwest (34% of total records). The water level products of  
327 BoM showed that, water level amplitude experienced a decrease from around 1.8 m on 16 April to around 0.5 m on 23 April  
328 (Fig. 11), which indicates that the tides became weaker and the vertical mixing induced by the tides would decrease a bit.

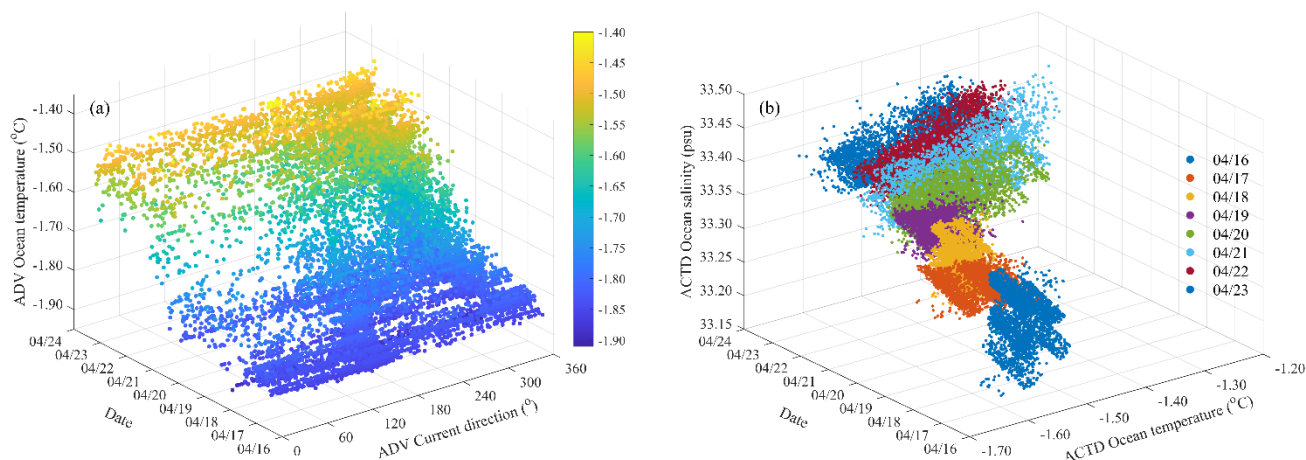

329

330 **Figure 11. Hourly water level merged by BoM product and harmonic constant calculation during 16 to 23 April**

331 The comparisons between current direction and temperature measured by ADV at 5 m beneath ice surface clearly showed that  
332 mean temperature for the southeast current (120–150°) was the lowest, which was  $-1.80 \pm 0.11^\circ\text{C}$ . The average temperature for  
333 the offshore current in the northwest direction (300–330°) was the highest, at  $-1.67 \pm 0.13^\circ\text{C}$  (Fig. 12a). Those results indicated  
334 that currents from outer open water carried the colder water to the coast, causing the ocean temperature beneath the landfast  
335 ice decrease.

336

337 Figure 12b showed the ocean temperature and salinity evolution observed by ACTD located 2 m below the ice surface. Both  
338 ocean temperature and salinity an increase trend over time, gradually from low temperature and low salt ( $-1.59 \pm 0.02^\circ\text{C}$  and  
339  $33.30 \pm 0.02$  psu on 16 April) to high temperature and high salt ( $-1.40 \pm 0.03^\circ\text{C}$  and  $33.39 \pm 0.02$  psu on 23 April). These  
340 phenomena could be related to the weakening of tide vertical mixing during these periods.

341  
342 **Figure 12. (a) The 3-D evolution of ocean velocity and direction at 5 m beneath landfast ice obtained by ADV; (b) The 3-D time-**  
343 **dependent distribution of ocean temperature and salinity obtained by ACTD at 2 m beneath landfast ice.**

344 If assumed that there was no ocean temperature jump increase after the 20 April and it remained stable at  $-1.59^{\circ}\text{C}$ , just as the  
345 average ocean temperature before 20 April, then the mean oceanic heat flux from 20 to 23 April would be  $29.66 \pm 10.59 \text{ W m}^{-2}$ ,  
346  $^2$ , which was 33% smaller than the measured oceanic heat flux of  $44.64 \pm 17.50 \text{ W m}^{-2}$  during the same period. Landfast ice  
347 would froze more 0.36 cm at the bottom from 20 to 23 April if no ocean temperature jump increase, against to the 2 cm melt  
348 observed by SIMBA after 20 April. Therefore, tides transformation would influence the ocean current, temperature, and  
349 salinity beneath landfast ice and then oceanic heat flux, finally impacted the evolution of ice mass balance. The observations  
350 with high sampling frequency help to refine the oceanic heat flux variation at the sub-diurnal scale and better demonstrate the  
351 influence of tides on oceanic heat flux.

#### 352 4.2 Comparisons with previous studies

353 Previous studies have estimated the oceanic heat flux under landfast ice in Antarctica with different methods and data intervals.  
354 Allison (1981) estimated oceanic heat flux near Mawson Station from monthly mean temperature and ice growth. At the early  
355 stage of sea ice growth, the thermohaline convection caused by the brine rejection makes the flux very high, could be as high  
356 as  $50 \text{ W m}^{-2}$ . Heil et al. (1996) used a multilayer thermodynamic model to simulate sea ice growth at Mawson Station. The  
357 multi-year averaged oceanic heat flux estimated by daily values was  $7.9 \text{ W m}^{-2}$ , and the annual mean was between 5 and  $12 \text{ W}$   
358  $\text{m}^{-2}$  from 1958 to 1986. Lei et al. (2010) estimated the oceanic heat flux using 30 minutes ice records in 2006, and the 5 day  
359 running mean oceanic heat flux in early April to be about  $15\text{--}20 \text{ W m}^{-2}$ . Yang et al. (2016) estimated the oceanic heat flux near  
360 Zhongshan Station by a thermodynamic model and the results was about  $25 \text{ W m}^{-2}$  in March and April. According to the  
361 weekly observation near Zhongshan Station, Zhao et al. (2019) interpolated and calculated the daily oceanic heat flux from  
362 March to May to be about  $30.0 \text{ W m}^{-2}$ . In this study, the averaged oceanic heat flux calculated by the residual energy method

363 and the bulk parameters method was based on a higher temporal resolution observation (2 minutes interval) and the results  
364 was about 32–34 W m<sup>-2</sup> during the study (16 to 23 April), consistent with the previous studies.

## 365 **5 Conclusions**

366 The heat balance between atmosphere, ice, and ocean was one of the most important processes in the Polar Regions. The  
367 interaction at the atmosphere–ice interface has been well investigated, however the interaction at ice–ocean interface was rarely  
368 studied because of the limit of underwater observations. Oceanic boundary layer regimes beneath sea ice plays an important  
369 role on the growth and melting of sea ice. In this study, an integrated ice–ocean observation system including ADV, ACTD,  
370 and SIMBA were deployed near Zhongshan Station in Prydz Bay, East Antarctica. The minute-resolution ocean temperature,  
371 salinity, density, current, and heat flux were analysed and investigated in this paper for the first time in this region.

372

373 The 4.8 m long SIMBA temperature chain recorded vertical temperature profiles of air–snow–sea ice–ocean, which was used  
374 to estimate snow and ice thickness. The results show that landfast ice froze 2 cm at the bottom during 16–20 April, while  
375 melted by 2 cm during 21–23 April. ACTD recorded high frequency ocean temperature and salinity at 5 m depth beneath  
376 landfast ice. The mean ocean temperature showed a jump increase from  $-1.59\pm 0.03^{\circ}\text{C}$  during 16–19 April to  $-1.47\pm 0.07^{\circ}\text{C}$   
377 during 20–23 April. The mean ocean salinity was  $33.53\pm 0.03$  psu with an overall increasing trend of  $0.013$  psu day<sup>-1</sup> during  
378 16–23 April, while the growth rate was slowing down during 20–23 April, because the melting of ice bottom shut down the  
379 salt rejection related to ice freezing. The mean ocean density was  $1026.84\pm 0.02$  kg m<sup>-3</sup>, which increased slightly during the  
380 study period. The ocean current recorded by ADV showed that 34% of the current direction was northwest (300–330°) and the  
381 mean velocity was  $3.13\pm 1.63$  cm s<sup>-1</sup>, with a maximum up to 11.25 cm s<sup>-1</sup> for 2 min time series and 10.23 cm s<sup>-1</sup> for 1 hour  
382 mean time series.

383

384 The mean oceanic heat flux was estimated by the residual energy method and the bulk parameters method. The results showed  
385 a range of 7.64–97.88 W m<sup>-2</sup> during the study period, with a mean of  $34.95\pm 17.52$  W m<sup>-2</sup> and  $32.26\pm 18.07$  W m<sup>-2</sup>, respectively  
386 for these two methods. Our results were consistent with previous studies, which usually was based on low frequency  
387 observations. The oceanic heat fluxes increased to twice after 20 April, which was related to the increase of ocean current  
388 velocity (from 2.68 cm s<sup>-1</sup> to 3.65 cm s<sup>-1</sup>) and the rise of ocean temperature (from  $-1.59$  to  $-1.47^{\circ}\text{C}$ ). The increase of oceanic  
389 heat flux triggered basal melt and decrease the landfast ice thickness by 2 cm.

390

391 The tide transform from semi-diurnal to diurnal during the study period was possibly attribute to the significant rise of ocean  
392 temperature. From 16 to 23 April, the tidal amplitude weakened and the period of current variation became longer, which  
393 indicated that the ocean currents influenced by the coastal tide, played an important role on the ocean temperature, and then  
394 further affected the oceanic heat flux.

395

396 In this study, the high frequency of oceanic measurements provides us a chance to investigate the influences of oceanic regimes  
397 beneath landfast ice in the diurnal scale. The bulk parameterization estimated the oceanic heat flux in more details than the  
398 residual energy method. However, the analysis was limited to a short time in the initial stage of sea ice growth because of the  
399 equipment malfunction. In future, we will carry out a longer field observation, to obtain a seasonal time series of ocean regimes  
400 beneath landfast ice and further explore the detailed impact of oceanic heat flux on the growth of sea ice.

401

#### 402 **Data availability**

403 Sea ice observed data are available upon request to the corresponding author.

404

#### 405 **Author contributions**

406 JC conceptualized this study and designed the numerical methods. HH carried out the experiments and wrote the manuscript.  
407 JC, PH and FH helped analyze the results and revised the manuscript. JM provided and helped process the sea ice observation  
408 data. XC assisted during the writing progress and critically discussed the contents.

409
