12

13 **Abstract**

14 Observations have confirmed basal melt rates of up to 16 m a⁻¹ underneath the Shirase ice tongue in
15 East Antarctica. These high basal melt rates are caused by intrusions of warm modified Circumpolar
16 Deep Water (mCDW) onto the continental shelf, a mechanism responsible for widespread mass loss
17 in West Antarctica, together with parts of Wilkes Land. In contrast to those regions, the catchment of
18 Shirase Glacier has been gaining mass, a trend attributed to increased precipitation. Here, we report
19 on the dynamical ocean-driven slowdown, thickening and grounding line advance of Shirase Glacier,
20 in response to strengthening easterly winds that reduce mCDW inflow and decrease basal melt rates.
21 Our findings are significant because they demonstrate that warm water regimes are not universally
22 associated with glacier acceleration and mass loss in Antarctica, and they highlight the overlooked
23 role of ocean forcing in the recent mass gain of the Dronning Maud Land sector.

24

25 **1. Introduction**

26 Shirase Glacier is the fastest flowing outlet glacier in East Antarctica, reaching speeds in excess of
27 2,200 m a⁻¹ across its grounding line, before flowing into Lützow-Holm Bay (Fig. 1). Its annual ice
28 discharge approaches 15 Gt a⁻¹ (Rignot et al., 2019) and it drains a catchment containing 1.2 m of sea
29 level equivalent (Fig.1, Morlighem et al., 2020). This rapid ice flow speed is associated with vigorous

30 melt underneath its floating tongue, where basal melt rates have been observed to vary seasonally
31 between 7 and 16 m a⁻¹ in 2018, 16 km downstream of the glacier's grounding line (Hirano et al.,
32 2020). These high melt rates are caused by warm modified Circumpolar Deep Water (mCDW)
33 intruding onto the continental shelf and being transported directly to the glacier via bathymetric
34 troughs (Fig. 1; Moriwaki & Yoshida, 1983; Hirano et al., 2020), a process referred to as Mode 2
35 melting (Jacobs et al., 1992). Elsewhere in Antarctica, most regions that experience this mode of
36 oceanic melt have been losing mass, as enhanced melt has thinned ice shelves, causing glacier
37 acceleration and mass loss e.g. the Amundsen Sea (Jenkins et al., 2018; Mouginit et al., 2014), the
38 Western Antarctic Peninsula (Cook et al., 2016) and Wilkes Land (Rintoul et al., 2016; Greene et al.,
39 2017). However, mass loss has not been observed at Shirase Glacier and, between 2003 and 2019, its
40 wider catchment (sometimes referred to as drainage basin 7) gained mass at a rate of $+25 \pm 6 \text{ Gt a}^{-1}$,
41 which is the largest imbalance of all drainage basins in East Antarctica (Smith et al., 2020), including
42 the comparatively well studied Wilkes Land (drainage basin 13; $-20 \pm 14 \text{ Gt a}^{-1}$).

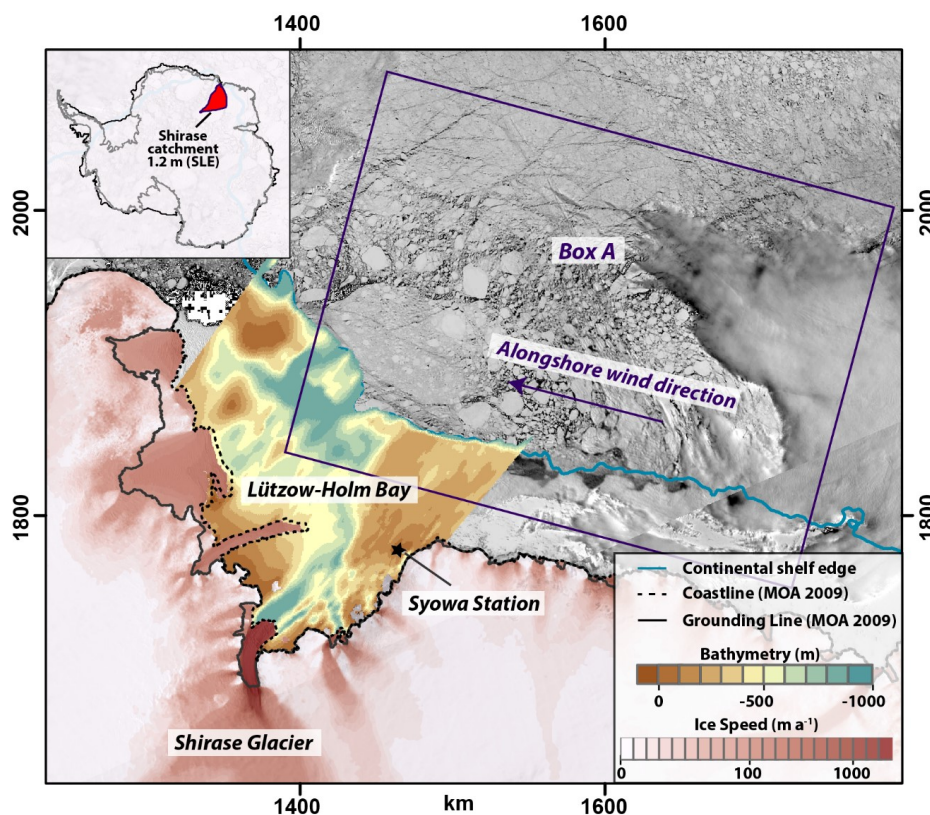

43 The mass gain and thickening in the Shirase catchment over the past two decades has been
44 hypothesized to have been caused by increased precipitation (Schröder et al., 2019; Smith et al., 2020)
45 from extreme snowfall events within the wider region (Boening et al., 2012; Lenaerts et al., 2013).
46 Although, earlier field-based estimates, using repeat triangulation surveys in 1969 and 1973,
47 demonstrated ice surface lowering of around 0.7 m a⁻¹ around 100-200 km inland of the Shirase
48 Glacier grounding line (Mae & Naruse, 1978; Naruse, 1979; Nishio et al., 1989). Furthermore, repeat
49 GPS surveys in 1980 and 1988 revealed a thinning rate of around 0.5 m a⁻¹ 100-150 km inland of the
50 grounding line (Toh et al., 1992). These rates of surface lowering during that time are comparable
51 with some of the fastest rates of thinning observed across Antarctica over the past decade at similar
52 distances inland of the grounding line (Smith et al., 2020). This surface lowering may have a much
53 longer-term signal with ice core records estimating a surface lowering of 350 m over the past 2000
54 years of the Mizuho Plateau (Kameda et al., 1990), which is located around 200 km inland of the
55 Shirase coastline. The surface lowering over the past 2000 years is coincident with an increase in ice
56 discharge from the Lützow-Holm Bay, which has been estimated from subglacial erosion rates
57 (Sproson et al., 2021).

58 Oceanographic observations in Lützow-Holm Bay in 2018 have revealed a two-layered structure with
59 a cool and relatively fresh layer of Winter Water overlying a warm and saline mCDW layer, where
60 temperatures near the ice front seasonally exceed the *in situ* melting point by 2.7 °C (Hirano et al.,
61 2020). Observations and modelling demonstrate a strong seasonal variation in the basal melt rate of
62 the Shirase ice tongue (Hirano et al., 2020; Kusahara et al., 2021), which is caused by seasonal
63 variations in the depth of the thermocline forced by the strength of the alongshore easterly winds near

64 the continental shelf (Ohshima et al., 1996). There is no evidence of large seasonal variations in ice
65 flow speed at the grounding line, but observations do show some seasonal variation in ice flow speed
66 on the floating tongue that could be connected to external forcing (Nakamura et al., 2007; 2010).

67 There have been several studies analysing the ice flow dynamics of the Shirase Glacier, largely
68 covering short sub-decadal time periods (Pattyn & Derauw, 2002; Pattyn & Naruse, 2003; Nakamura
69 et al., 2010; Aoyama et al., 2013). However, the longer-term geological signal of ice sheet thinning
70 and increased ice discharge, along with observations of thinning in the 1970s and 1980s, followed by
71 thickening from the 2000s raise some important questions into the processes causing this switch. In
72 this study, we produce a time series of ice flow speed that spans 47 years and show that long-term ice
73 speed trends coincide with alongshore wind speeds. We then discuss how these observations may
74 relate to wider hemispheric trends in atmospheric circulation and what this may mean for the future
75 mass balance of the Shirase catchment and the wider Dronning Maud Land sector.

76

77 **Figure 1:** MODIS image of Lützow-Holm Bay and Shirase Glacier from the 4th November 2019
78 obtained from NASA WorldView. Overlain is the ITS_LIVE composite velocity product in
79 logarithmic scale (Gardner et al., 2018; 2020), the MODIS 2009 grounding line and coastline (black
80 line; Scambos et al., 2007; Harran et al., 2019), 1000 m bathymetric contour obtained from

81 BedMachine (Morlighem et al., 2020) which is taken as the continental shelf boundary and
82 bathymetry of the Lützow-Holm Bay (Kusahara et al., 2021). Note the deep trough connecting Shirase
83 Glacier to the open ocean. The location of the Syowa research station and Box A, the region where
84 ERA5 derived winds were extracted are also shown. The coordinate grid is in km and it is projected
85 in Polar Stereographic.

86

87 **2. Data and Methods**

88 **2.1 Ice-front position, ice speed, grounding line and ice thickness**

89 We create a time series of ice-front positions between 1963 and 2020 using a variety of different
90 sources including: ARGON imagery from 1963, Landsat-1 imagery from 1973, Landsat-5 imagery
91 from 1984, Landsat-4 imagery from 1988, RADARSAT RAMP mosaic from 1997 (Jezek et al.,
92 2013), and MODIS imagery from 2000-2020, with the spatial resolution of the satellite data ranging
93 from 15-250 m. In each case, we map the outer limit of the collection of loosely bound icebergs that
94 form the Shirase ice tongue that are typically surrounded by a smoother surface of fast ice (Fig. 1 &
95 2a). Errors associated with this mapping are insignificant in the context of the ice tongue typically
96 advancing 2,500 m a⁻¹, or retreating in short-lived calving events typically >10 km.

97 We calculate 18 ice speed estimates for Shirase Glacier between 1973 and 2020. For 1973 we use a
98 pair of Landsat-1 (band 7) images from the 25th January 1973 and the 21st January 1974 that we
99 manually co-register to each other, before co-registering to a Landsat-8 image. The combination of
100 the relatively coarse Landsat-1 imagery (60 m) and the development of surface melt ponding over the
101 fast flowing section of the glaciers between the two images prevented the automatic extraction of ice
102 speed. Instead, we extract an ice speed estimate by manually tracking the displacement of a prominent
103 rift ~24 km downstream of the grounding line (Fig. 2c). Errors associated with the manual tracking
104 of this rift stem from the co-registration between the two image pairs which we estimate to be one
105 pixel (60 m; Animation S1). For 1988, we use a pair of Landsat-4 (band 3) images from the 14th
106 January 1988 and the 15th February 1988 that we also co-register to a Landsat-8 image. The quality
107 of the Landsat-5 images (30 m resolution) is superior to that of the Landsat-1 imagery and, in the
108 absence of significant surface melt ponding, we use the feature tracking software COSI-CORR
109 (Leprince et al., 2007; Scherler et al., 2008) to extract ice speed. For these images co-registration
110 error is negligible (Animation S2) and error in the feature tracking is estimated at <0.5 pixels (e.g.
111 Heid and Kääb, 2012), because of the close time separation of the image pairs this results in a larger
112 error of ±171 m a⁻¹. For 2000-2018 we use 14 annual ice speed mosaics from the ITS_LIVE dataset
113 which cover Shirase Glacier (Gardner et al., 2018) and use the corresponding error grids for error
114 values, which range from 1 to 32 m a⁻¹. For 2019 (n=27) and 2020 (n=19) we take an average for all

115 GoLIVE generated ice speed fields (Fahnestock et al., 2016; Scambos et al., 2016) with a time
116 separation of 16-320 days from scene ID's 149_109 and 150_109. Taking an average of multiple ice
117 speed grids reduces error and, as such, we prescribe a nominal error of 16 m a^{-1} . We extract ice speed
118 profiles from each time period across a transect, T1 (Fig. 2a), and also produce a time-series of ice
119 speed change where T1 crosses the grounding line. In 1973, the only possible observation of ice speed
120 was extracted 24 km downstream of the grounding line (Point x; Fig. 2a) and there are no observations
121 directly at the grounding line. To account for this, we estimate ice speed at the grounding line in 1973
122 using the average difference between point x, 24 km downstream of the grounding line, and where
123 T1 crosses the grounding line in each of the other 17 ice speed profiles (1988-2020). Across these
124 profiles, ice speed was on average 2% slower (ranging from 1% to 4%) at the grounding line,
125 compared to ice speed at point x. Therefore, to estimate ice speed at the grounding line in 1973 we
126 reduce the ice speed observed 24 km downstream of the grounding line by $2 \pm 1\%$. We also include
127 the measurements of ice speed from Nakamura et al. (2007) at the grounding line derived from the
128 JERS-1 satellite in 1996, 1997 and 1998.

129 To estimate the direction and magnitude of any migration in the Shirase Glacier grounding line we
130 compare time stamped digital elevation model (DEM) strips with a spatial resolution of 2 m from the
131 6th January 2013 and the 8th October 2015 from the REMA project (Howat et al., 2019). We select
132 these strips because they cover the complete Shirase Glacier grounding line and represent the longest
133 time gap in the record. This is in addition to a SPOT5-HRS DEM from the SPIRIT project (Korona
134 et al., 2009) from the 8th February 2008, with a spatial resolution of 40 m. Elevation uncertainty is
135 estimated at around 4 m by comparing derived elevations from exposed bedrock between the two
136 REMA DEM's and a larger uncertainty of around 7 m between the SPOT5-HRS and REMA DEM's.
137 The tidal amplitude of the region is limited to 0.2 m (Aoki et al., 2000) and is deemed insignificant.
138 We extract elevation profiles along transect T1 (Fig. 2a) from these dates. A comparison of elevation
139 profiles cannot provide a location of the true grounding line position, but any horizontal migration of
140 these elevation slopes can provide reasonable estimates in both the direction and rate of grounding
141 line migration (Fricker et al., 2009; Brunt et al., 2010).

142 We also extract an ice thickness change time-series from the dataset presented in Schröder et al.
143 (2019) from point IT, which is around 20 km inland of the grounding line (Fig. 2a). This multi-
144 mission dataset spans between 1978 and 2017 and contains data from a variety of satellites. We use
145 the accompanying uncertainty estimates described in Schröder et al. (2019). We also utilize modelled
146 melt rate anomalies of the Shirase ice tongue that are derived by an ocean model that is forced by
147 ERA5 wind reanalysis between 2008 and 2018 by Kusahara et al. (2021). The melt rate dataset
148 contains melt anomalies that have been simulated with and without fast ice cover, we use the melt

149 rates with fast ice cover, but note that there is little difference between the two melt rate datasets (see
150 Fig. 20; Kushara et al., 2021)

151

152 2.2 Climatological data

153 We extract mean monthly ERA5 (Hersbach et al., 2020) 10 m zonal (U) and meridional winds (V)
154 speeds with a gridded 30 km spatial resolution between 1979 and 2020 from an approximately 340 x
155 250 km box adjacent to the coastline (Box A; Fig. 1). We do not extend the box all the way into
156 Lützow-Holm Bay because it is semi-permanently covered with landfast sea-ice (Fig. S1) that
157 dampens the impact of winds on ocean circulation. We also utilize an observational wind direction
158 and wind speed time-series (1966-2020) from the Syowa research station (See Fig.1) that is available
159 via the SCAR Met READER (Turner et al., 2004). We then calculate alongshore easterly wind speed
160 for both the ERA5 reanalysis data extracted from Box A and the observational time-series from
161 Syowa research station, using an alongshore angle of 80° from due north:

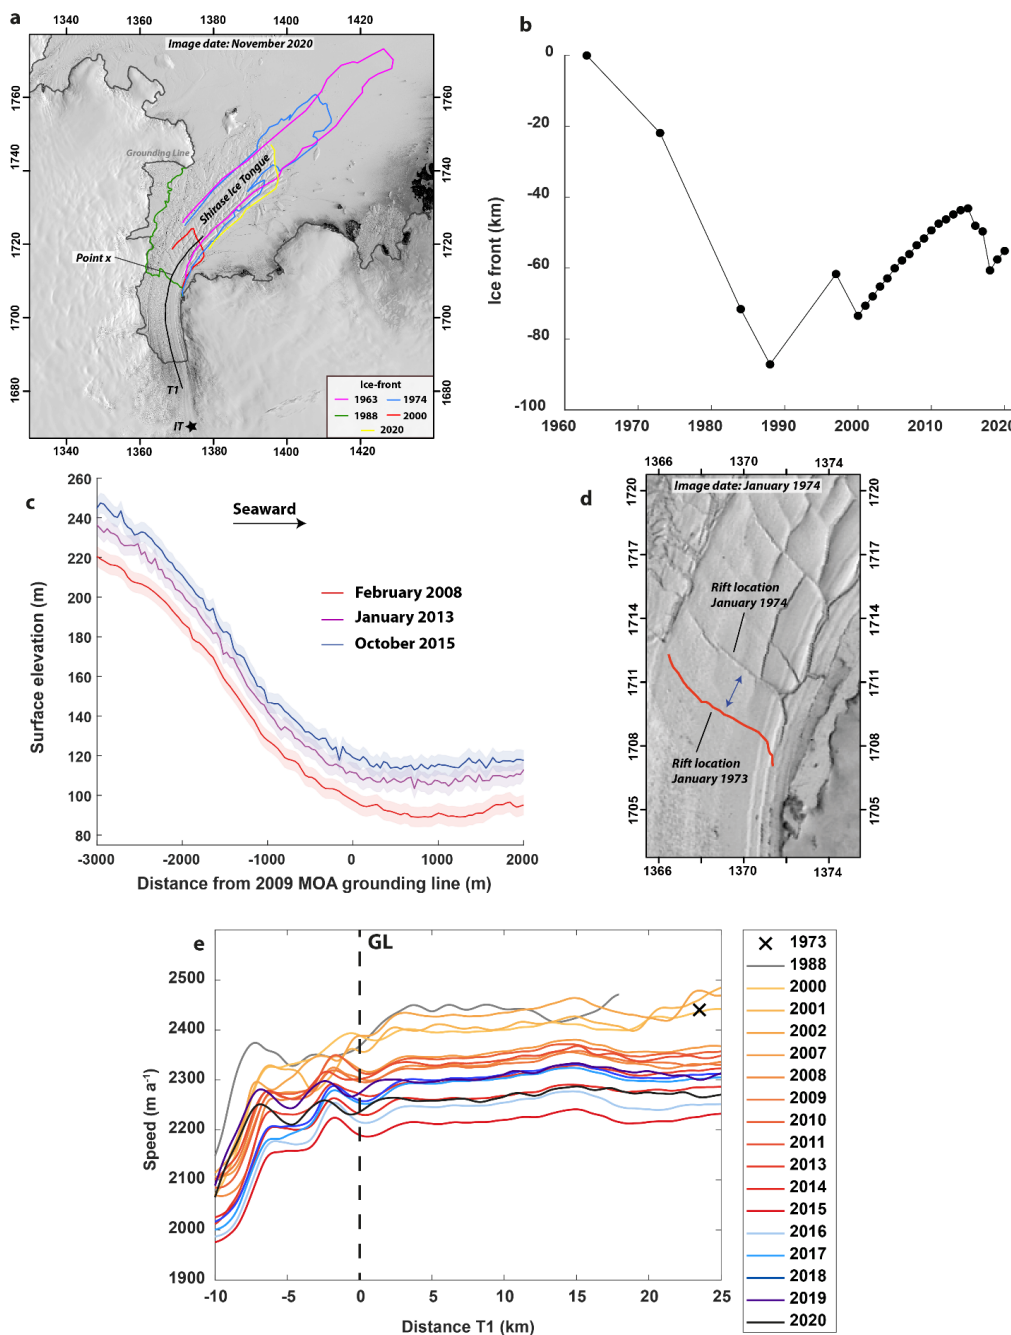

$$162 \quad A = W \cos(\theta - 80)$$

163 Where W is wind speed and θ is wind direction. Some differences between the ERA5 and
164 observational record from Syowa are expected because the ERA5 record represents an average from
165 a much larger region, while the observational data from Syowa research station are from a single
166 spatial location.

167

168 3. Results

169 We observe a total range of nearly 90 km in the ice-front position of the Shirase ice tongue between
170 1963 and 2020. Its maximum extent was in 1963, before retreating to its minimum extent in 1988
171 (Fig. 2a, b). Since 1988 there has been a general pattern of advance with a few sporadic calving events
172 (Fig. 2a, b). Most of the variation in the extent of the Shirase ice tongue is in the heavily fractured
173 and unconstrained section of the floating ice tongue. The only exception to this was in 1988 when the
174 ice tongue retreated to the entrance of the narrow and more constrained section of its fjord, 24 km
175 advanced of its 2009 grounding line (Fig. 2a).

176

177 **Figure 2:** a) Landsat-8 image from November 2020 showing the Shirase ice tongue. Overlain are
 178 selected ice-front positions from 1963, 1974, 1988, 2000 and 2020; along with the transect, T1, used
 179 to extract ice speed profiles and point x, which is the location of the 1973/74 ice speed estimate on
 180 the floating tongue. Point IT is the location of the ice thickness time-series. The grey line is the
 181 MODIS 2009 grounding line (Scambos et al., 2007, Harran et al., 2021). The coordinate grid is in

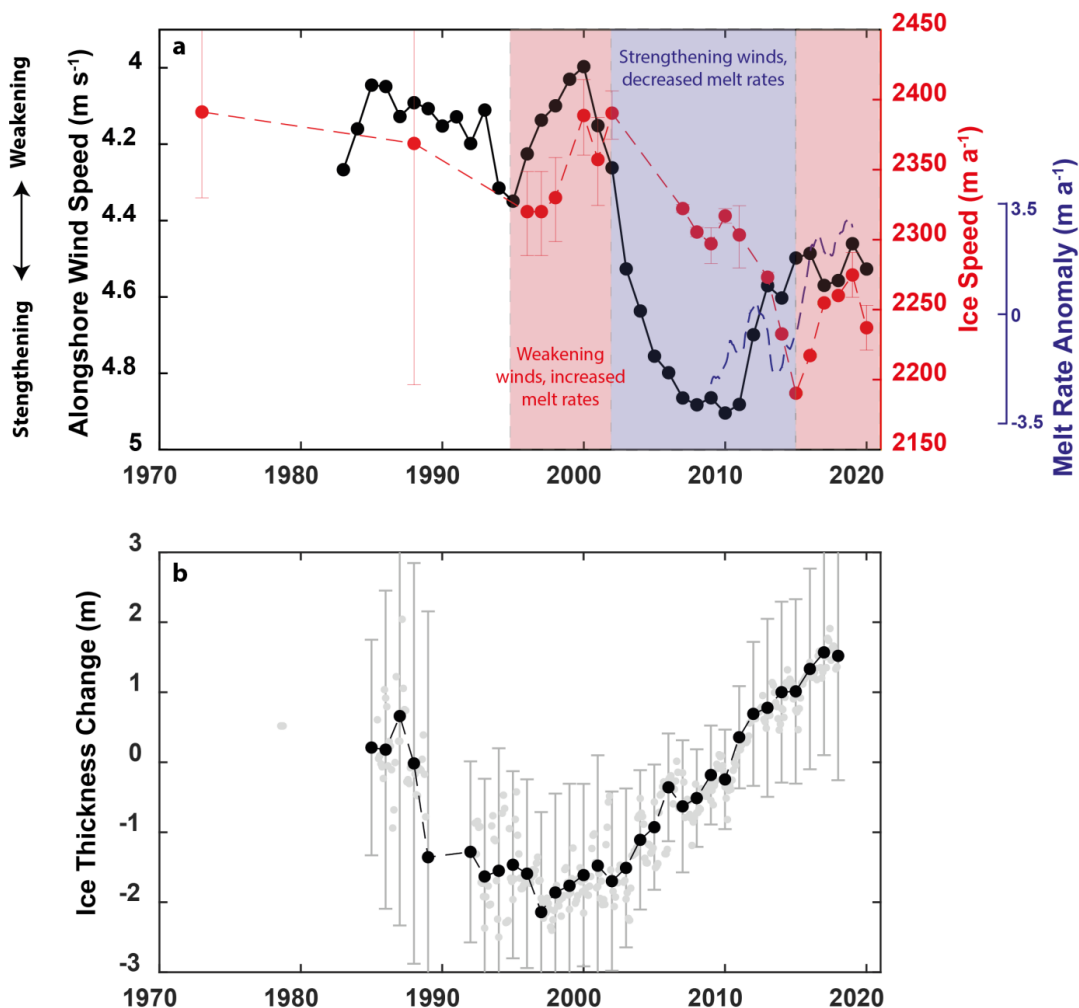

182 km. **b)** Change in ice-front extent relative to 1963. **c)** Surface elevation profiles along a small section
183 of T1 as it intersects the grounding line from February 2008, January 2013 and October 2015 showing
184 a seaward migration of the surface slope **d)** The rift used to estimate ice speed in 1973/74. The red
185 line is the digitized rift from January 1973. **e)** Ice speed profiles from transect T1 between 1973 and
186 2020. The black cross represents the ice speed measurement from 1973/74. Landsat images are
187 courtesy of the U.S. Geological Survey.

188

189 Ice speed profiles along the transect (T1, Fig. 2a) show a uniform pattern of change across both the
190 grounded and floating sections of Shirase Glacier (Fig. 2e). At the grounding line, we observe little
191 change in ice speed between 1973 and 1988, although we note the larger uncertainty in the 1988
192 estimate of $\pm 171 \text{ m a}^{-1}$ (Fig. 3b). Between 1988 and 1996 we observe a $2 \pm 7\%$ slowdown and a $2 \pm 1\%$
193 increase in ice speed between 1997 and 2000 (Fig. 3a). Post-2000 we observe a slowdown, with an 8
194 $\pm 1\%$ decrease in ice speed between 2000 and 2015 (Fig. 3b). Between 2015 and 2019 ice speed
195 increased by $4 \pm 1\%$ (Fig. 3a). Elevation profiles along a section of T1 in 2008, 2013 and 2015 show
196 a seaward migration of the surface slope as it approaches the grounding line (Fig. 2d), which is
197 indicative of grounding line advance and can be visualised in animation S3. Between February 2008
198 and October 2015 we estimate that the grounding line has advanced around 400 m ($\sim 50 \text{ m yr}^{-1}$) from
199 measuring the seaward displacement of the surface slope, an estimate that is consistent with CryoSat
200 based observations of seaward grounding line migration between 2010 and 2016 ($\sim 30 \text{ m a}^{-1}$; Konrad
201 et al., 2018). Observations of ice thickness change 20 km inland of the grounding line show a thinning
202 trend of $0.27 \pm 0.33 \text{ m a}^{-1}$ between 1987 and 1997, before reversing to a thickening trend of 0.19 ± 0.10
203 m a^{-1} between 1997 and 2017 (Fig. 3b).

204 ERA5 derived estimates of alongshore wind speed between 1979 and 2020 show limited variation
205 between 1984 and the early 1990s (Fig. 3a). In the early 1990s there was a small increase in
206 alongshore wind speed, before a much more marked increase from 2000-2010 where alongshore wind
207 speed increased from around 4 m s^{-1} to 4.8 m s^{-1} (Fig. 3a). This is before falling slightly to around 4.5
208 m s^{-1} between 2010 and 2018, which is coincident with an increase in basal melt rate anomalies (Fig.
209 3a). Long-term increased alongshore wind speeds at the Syowa research station in Lützow-Holm Bay
210 between 1966 and 2020 are also observed with a small peak in alongshore wind speeds in the early
211 1990s before a sharp increase in along shore wind speed between the late 1990s and 2005 (Fig. S2).
212 However, the observational record at Syowa also records a peak in alongshore wind speed in the early
213 1980s (Fig. S2) that is not present in the ERA5 offshore reanalysis record (Fig. 3a).

214

215

216 **Figure 3: a)** Annually averaged ERA5 derived alongshore wind speed from Box A (See Fig. 1) and
217 plotted as a 5-year rolling mean (black), ice speed at the Shirase Glacier grounding line along T1
218 (red) and modelled melt rate anomaly of the Shirase ice tongue between 2008 and 2018 (blue;
219 Kusahara et al., 2021). Periods of weakening winds cause increased mCDW transport, increased basal
220 melt and acceleration. Periods of strengthening winds result in relatively less mCDW transport,
221 decreased basal melt rates and glacier slowdown. Note that alongshore wind speed is plotted with an
222 inverted axis. **b)** Annually averaged ice thickness change at point IT (see Fig. 2a) extracted from the
223 Schröder et al. (2019) dataset, where there are at least 6 data points in the calendar year. The error
224 bars are annually averaged errors. The background grey points are the raw monthly data points.

225

226 4. Discussion

227 4.1 Slowdown and thickening caused by strengthening alongshore winds

228 Theoretical considerations indicate that the heavily fractured and unconstrained section of the Shirase
229 ice tongue offers little buttressing force (Fürst et al., 2016). Therefore, it is unlikely that any variations
230 in the extent of the Shirase ice tongue have had a direct effect on the ice speed trends we have
231 observed (Fig. 4a). The only exception to this is in 1988 where the ice tongue briefly retreated to the
232 edge of its more confined embayment (Fig. 2a), closer to where the extent of the ice tongue might be
233 expected to exert buttressing and impact on inland flow speed, were it to be removed (Fig. 4a).

234

235

236 **Figure 4:** No change in ice tongue buttressing in response to observed changes in ice tongue extent,
237 but increased buttressing expected in response to observed ice tongue thickening. **a)** Simulated
238 maximum buttressing potential of the Shirase ice tongue (Durand et al., 2016). Light blues mean the
239 ice is passive, purples mean the floating ice is dynamically important. No dynamically important ice
240 has calved over the past over the past 57 years. **b)** Ice tongue thickness change between 2003 and
241 2019 showing thickening of the Shirase ice tongue (Smith et al., 2020). **c)** Simulated response of ice
242 flux to thinning of floating ice in each grid cell by 1 m (Reese et al., 2018), floating ice near the
243 grounding line is important for buttressing.

244

245 In agreement with previous work, we note that the observed fluctuations in ice tongue extent are
246 correlated with landfast sea-ice conditions in Lützow-Holm Bay (Aoki, 2017). Long periods of ice
247 tongue advance are associated with persistent landfast sea-ice in Lützow-Holm Bay, while ice tongue
248 retreat is associated with landfast sea-ice break-out events removing parts of the ice tongue
249 conglomerate (Aoki et al., 2017). It is unlikely that the fast ice has any major role in providing
250 buttressing for Shirase Glacier. We note that there was no obvious spike in ice speeds on the
251 grounding line or ice tongue in 1988 when the fast ice was completely removed from the bay (Fig.
252 2a, S3) and that Nakamura et al. (2010) recorded only a very modest $20 \pm 30 \text{ m a}^{-1}$ ($0.8 \pm 1.3 \%$)
253 change in ice speed at the grounding line after a partial fast ice break-out event in 1998.

254 Point IT, 20 km inland of the Shirase Glacier grounding line was thinning at a rate of -0.27 ± 0.33 m
255 a^{-1} between 1987 and 1997 (Fig. 3c), a pattern consistent with field observations up to 200 km further
256 inland in the 1960s, 1970s and 1980s (Mae and Naruse, 1978; Naruse, 1979; Nisho et al., 1989; Toh
257 and Shibuya, 1992). However, at ~ 2000 there was a slowdown in Shirase Glacier (Fig. 3a) and this
258 thinning trend reversed to thickening (Fig. 3b). This slowdown and thickening coincides with an
259 increase in alongshore wind speed adjacent to the Shirase coastline (Fig. 3a). The seasonal
260 strengthening in alongshore winds offshore of the Shirase coastline has been observed to deepen the
261 thermocline in Lützow-Holm Bay, limiting the inflow of mCDW onto the continental shelf and reduce
262 basal melt rates (Hirano et al., 2020). We suggest that this same process over annual to decadal
263 timescales has caused the slowdown of Shirase Glacier.

264 Increased alongshore wind speed from ~ 2000 enhanced Ekman convergence at the coast, deepening
265 the thermocline with a short lag and inhibited the inflow of warm mCDW into Lützow-Holm Bay.
266 The subsequent cooling of Lützow-Holm Bay reduced the basal melt rate of the Shirase ice tongue.
267 This reduction in basal melt caused the ice tongue to dynamically thicken and is confirmed by ICESat
268 and ICESat-2 observations of the of the Shirase ice tongue that show a mean thickening of 1.87 m yr^{-1}
269 1 from 2003-2019 (Fig. 4b; Smith et al., 2020). The dynamic thickening of the ice tongue increases
270 buttressing through time (Reese et al., 2018; Fig. 4c) and ultimately drives the overall slowdown in
271 ice speed, grounding line advance and inland thickening that we observe. Importantly, our results
272 show that wind-driven ocean forcing is also contributing to the mass gain in the Dronning Maud Land
273 regions in addition to surface mass balance processes (Boening et al., 2012; Lenaerts et al., 2013).

274 Within the longer term slowdown of Shirase Glacier between 1973 and 2020 we observe brief periods
275 of acceleration in response to short-lived periods of weakening alongshore winds. For example, both
276 of the accelerations in ice speed from 1997-2000 and 2015-2019 are preceded by brief periods of
277 weakening alongshore winds (Fig. 3a). These periods of weakening alongshore winds cause relatively
278 higher basal melt rates because they raise the thermocline closer to the ocean surface and enable a
279 greater influx of mCDW into Lützow-Holm Bay (Hirano et al., 2020). For 2015-2019, this is
280 supported by increasingly higher modelled melt rate anomalies (Fig. 3a). Because we observe
281 coincidental acceleration in ice speed during this period of increased melt rates, it is indicative of a
282 reduction in buttressing in response to ice tongue thinning. The interannual variability in ice flow
283 speed at Shirase Glacier in response to wind-forced ocean variability is analogous to other regions of
284 Antarctica where mCDW periodically floods the continental shelf e.g. Pine Island (Christianson et
285 al., 2016), Thwaites (Miles et al., 2020) and Totten Glaciers (Greene et al., 2017). Although, the
286 pattern of change at Shirase Glacier is unique because it is the only outlet glacier in Antarctica with
287 a warm water regime, that has been observed to be slowing down and thickening during the 21st

288 century, as opposed to accelerating and thinning (e.g. Mouginot et al., 2014; Greene et al., 2017).
289 Therefore, this result highlights that this oceanic mode of ice melt is not universally associated with
290 mass loss in Antarctica.

291

292 **4.2 Wider links to climate forcing and future implications**

293 In response to both increased greenhouse gas emissions and ozone depletion (Thompson et al., 2011;
294 Wang et al., 2014; Perren et al., 2020) the band of mid-latitude westerly winds that encircle Antarctica
295 have both strengthened and migrated southwards towards the ice sheet over recent decades
296 (Thompson & Solomon, 2002; Marshall, 2003; Turner, 2005; Bracegirdle et al., 2018). In the
297 Amundsen Sea sector this anthropogenic driven migration has been linked to westerly wind anomalies
298 over the continental shelf (Holland et al., 2019), which have enabled a greater influx of warm mCDW
299 onto the continental shelf and have driven enhanced localized ice sheet mass loss (Thoma et al., 2008).
300 At Shirase Glacier, our observations of strengthening alongshore easterly winds suggest any
301 southward encroachment of the mid-latitude westerlies has yet to impact the Shirase coastline. This
302 may also be the case for parts of the wider Dronning Maud Land coastlines where alongshore
303 easterlies have also been observed to have strengthened (Hazel & Stewart, 2019). This trend in
304 strengthening alongshore easterlies is linked to enhanced katabatic winds as low pressure systems
305 track progressively further south and enhance the pole to coast pressure gradient (Hazel & Stewart,
306 2019). It remains undetermined if the enhancement of the pole to coast pressure gradient has been
307 influenced by the anthropogenically driven southerly migration of the mid-latitude westerlies, or if it
308 has been caused by inherent natural decadal variability within the system.

309 Over the course of the 21st century, the southerly migration of the mid-latitude westerlies is projected
310 to continue in line with a warming climate (Yin, 2005; Perren et al., 2020). Along the Shirase
311 coastline, it remains unclear if this continued southerly migration will ultimately result in a similar
312 situation to the Amundsen Sea, such that westerly wind anomalies offshore would result in enhanced
313 mCDW transport into Lützw-Holm Bay and cause mass loss. Alternatively, the westerly winds may
314 never migrate close enough to the Shirase coastline to impact alongshore winds, and instead,
315 alongshore winds may continue to strengthen as the pole to coast pressure gradient increases. This
316 would result in further cooling of Lützw-Holm Bay and ice tongue thickening, and further mass
317 gain. In a wider context a greater understanding of the potential changes in ocean forcing in response
318 to broader atmospheric patterns expected over the coming decades is needed in the Dronning Maud
319 Land sector.

320

321 **5. Conclusion**

322 Our observations of Shirase Glacier are a rare example of a glacier reversing a trend of mass loss
323 from at least the 1970s-1990s to mass gain over the last two decades. As far as we are aware this is
324 the only major fast flowing Antarctic outler glacier to display this pattern of behaviour. This reversal
325 has been driven by a slowdown of the Shirase Glacier upstream of the grounding line in response to
326 strengthening alongshore winds that have limited the inflow of warm mCDW into Lützow-Holm Bay,
327 reduced basal melt rates and caused its ice tongue to dynamically thicken. This means that ocean
328 forcing has contributed to some of the observed mass gain in Dronning Maud Land. It is not certain
329 if these strengthening alongshore winds represent some form of inherent decadal-scale variability or
330 if they are part of a multi-decadal trend, but we hypothesise that they are at least consistent with an
331 anthropogenically-driven poleward migration of the mid-latitude westerly winds. Should this
332 strengthening of alongshore easterly winds continue into the future, the Shirase catchment will
333 continue to experience a positive mass balance due to both the slow-down in ice discharge, and to the
334 predicted increase in precipitation in response to atmospheric warming (e.g. Ligtenberg et al., 2013;
335 Kittel et al., 2021). Our results highlight the need for a greater consideration in the potential role of
336 ocean forcing in both the current and future mass balance of the wider Dronning Maud Land region.
