**Abstract.** Global warming causes many rockfall activities of the alpine mountains, especially when ice-filled joints in the rock mass become thawed. The warming and thawing of frozen soils and intact rocks were widely studied in the past several decades, however, the variation of shear strengths of ice-filled joints was not fully understood. In this study, a series of compression-shear experiments were conducted to investigate the shear strength of ice-filled rock joints by considering the effects of joint roughness, temperature, opening, shear rates and normal stress. The joint roughness can improve the shear strength of ice-filled joints. However, the contribution of joint roughness is controlled by some noticeable bulges instead of the JRC index. The shear strength linearly increases with increasing the aggregation of rupture ice area before these noticeable bulges. As the joint opening increases, the effect of joint roughness decreases and the shear strength of ice-filled joints tends to be equal to the shear strength of pure ice. In addition, the shear strength quickly reduces with increasing temperature from

21 -15 °C to -0.5 °C. The shear failure mode changes from shear cracking of joint ice to the shear  
22 debonding of ice-rock interface above -1 °C. Increasing shear rate will decrease the shear strength of  
23 ice-filled joints because the joint ice displays the brittle failure phenomenon at a high shear rate. The  
24 shear strength of ice-filled joints linearly increases with increasing the normal stress. Moreover, it is  
25 also proved that the Mohr-coulomb criterion can be used to characterize the shear strength of ice-filled  
26 joints under different normal stresses. This research can provide a better understanding of the warming  
27 degradation mechanism of ice-filled joints by considering the above important influencing factors.

## 28 **1 Introduction**

29 With the increase of global temperature and human activities in permafrost areas, many alpine rock  
30 masses become more unstable (Gruber and Haeberli, 2007; Allen and Huggie, 2013; Hartmeyer et al.,  
31 2020; Legay et al., 2021; Hilger et al., 2021). A large number of rockfalls in permafrost alpine bedrock  
32 slopes indicated the exposure of broken ice after shear failure, which could cause serious natural  
33 geological disasters (Krautblatter et al., 2021; Walter et al., 2019). For example, the rockfall disaster  
34 that happened in Chamoli, Indian Himalaya, in 2021 took more than 200 lives and destroyed two  
35 hydropower facilities (Shugar et al., 2021). According to investigation results, this rockfall disaster was  
36 caused by the warming and thawing of ice. It is evidenced that a huge frost heaving pressure will be  
37 produced to drive the voids and joints propagation and thus cause the instability of joint rock masses  
38 during the freezing process (Huang et al., 2022a; 2022b). Fortunately, the bonding strength between ice  
39 and joint wall can strengthen the joints themselves after complete freezing (Matsuoka and Murton,  
40 2008; Zhang et al., 2020; Shan et al., 2021; Wang et al., 2022). However, if the joint ice was thawed,  
41 the rock-ice-rock “sandwich” structure would be debonded and unstable. In addition, the liquid water

42 produced by warming ice could lower the friction between joint surface and thus reduced the stability  
43 of joint rock slopes (Zhao et al., 2017). Many field data showed that most of the irreversible fracture  
44 displacement and rockfall happened in the warm seasons instead of the cool seasons because the  
45 warming and thawing of joint ice could greatly decrease the strength of rock mass containing ice-filled  
46 joints (Weber et al., 2018; Etzelmüller et al., 2022). Yang et al. (2019) claimed that the existence of  
47 detached ice block could promote the mobility of ice-rock system and thus cause a more serious  
48 geological disaster on alpine rock slope. Therefore, the warming degradation of the ice-rock interface  
49 and the strength loss of ice-filled joints should be comprehensively studied.

50 In the past decades, the warming degradation of permafrost soils was widely investigated, however,  
51 there is little literature reporting the strength loss of rocks containing ice-filled joints. The shear  
52 experiment of the ice-rock interface might be first conducted by replacing the rock with concrete in  
53 order to make a specific roughness (Davies et al., 2001, 2017). These experiments were conducted at  
54 the temperature from -5 to 0 °C. Krautblatter et al. (2012) developed a shear strength model for the  
55 ice-filled joints that incorporates the cracking of rock bridges, the friction of rough joint walls, creep of  
56 ice and detachment of rock-ice interfaces. Mamot et al. (2018) conducted a systematic study of the  
57 shear failure of limestone-ice and mica-rich interfaces at constant strain rates from -10 to -0.5°C, and  
58 they found that the normal stress and freezing temperature were two important factors influencing the  
59 shear strength. However, the uniform joint surfaces were used without considering the influence of  
60 joint roughness. Mamot et al. (2021) further predicted the warming stability of permafrost slopes  
61 containing ice-filled joints by using the Universal Distinct Element Code (UDEC). The simulation  
62 results verified that the warming temperature close to the melting point might drive the slide of a slope

63 with angle of 50°-62°, and the actual slope angle also depended on the joint orientation. The above  
64 research mainly investigated the thawing temperature and normal stress on the shear strength of  
65 ice-filled joints. The highest normal stress is about 1.438 MPa (Davies et al., 2001), and the maximum  
66 range for the temperature was -10 °C to -0.5 °C (Mamot et al., 2018). However, the freezing depth  
67 could exceed 100 m for some alpine caves containing frozen ice (normal stress large than 2 MPa) and  
68 the temperature was less than -15 °C as observed in the field (Colucci and Guglielmin, 2019).  
69 Therefore, a much wider range of temperature should be considered when investigating the shear  
70 characteristics of ice-filled joints.

71 In addition, although some scholars began to pay attention to the mechanical properties of ice-filled  
72 joint rock mass, the influence of many important factors on the shear strength of ice-filled joints was  
73 not investigated, including the joint roughness, shear rate, normal stress and joint opening. Generally,  
74 the natural joints have different roughness and openings (Shen et al., 2020). In this study, a  
75 comprehensive shear experiment was performed on the ice-filled joints in sandstones. The main  
76 purpose was to reveal the influencing mechanism of freezing temperature, joint roughness, shear rate,  
77 joint opening and normal stress on the shear strength of ice-filled joints in rock masses. This research  
78 can provide a better understanding of the warming degradation process of the ice-filled joints and the  
79 thawing disaster of alpine mountains in cold regions.

## 80 **2 Materials and methods**

### 81 **2.1 Collection of sandstones**

82 The red sandstones collected from Yichang city of Hubei province were used in this experiment. This  
83 is a typical sedimentary rock and is widely distributed on the surface of the earth. The block samples

84 with approximately equal P-wave (compressional wave) velocities were chosen to make frozen samples  
 85 containing ice-filled joints. The basic physico-mechanical properties of this red sandstone are given in  
 86 Table 1.

87 **Table 1.** The basic physico-mechanical properties of the fresh sandstone.

Density ( $\rho$ ) (g/cm <sup>3</sup> )	Porosity ( $n$ ) (%)	Primary wave velocity $V_p$ (m/s)		Shear strength $\tau_{ps}$ (MPa)		Uniaxial compressive strength UCS (MPa)	
		Dry	Saturated	Dry	Saturated	Dry	Saturated

## 89 **2.2 Preparation of ice-filled joint rock mass**

90 According to the JRC index proposed by Barton and Choubey (1977), five kinds of roughness were  
 91 used in this experiment, including No. 2 (2°-4°), No. 4 (6°-8°), No. 6 (10°-12°), No. 8 (14°-16°) and  
 92 No. 10 (18°-20°), respectively. The frozen samples containing ice-filled joints are made in the  
 93 laboratory because it is hard to cut or drill them in the fields. The manufacturing process of ice-filled  
 94 joint rock mass mainly includes the following steps:

95 ① The original rock blocks were cut into the designed rectangular blocks (100 mm × 100 mm × 50  
 96 mm) by using a rock cutting machine.

97 ② These rectangular blocks were used to engrave different rough curves on the surface by using a  
 98 3D numerical control engraving machine. The roughness can be controlled by implanting the standard  
 99 JRC curves into the controlling system of this machine. Each frozen rock sample containing an  
 100 ice-filled joint was assembled by using a pair of rectangular blocks with the same roughness.

101 ③ The rock blocks were heated in a dry oven at 105 °C in order to tightly paste the waterproof tape  
102 and prevent the escape of joint water during freezing.

103 ④ The joint opening was divided into different specified thicknesses which were controlled by  
104 inserting rubber strips, and a piece of waterproof tape was pasted on the surface in order to store water.

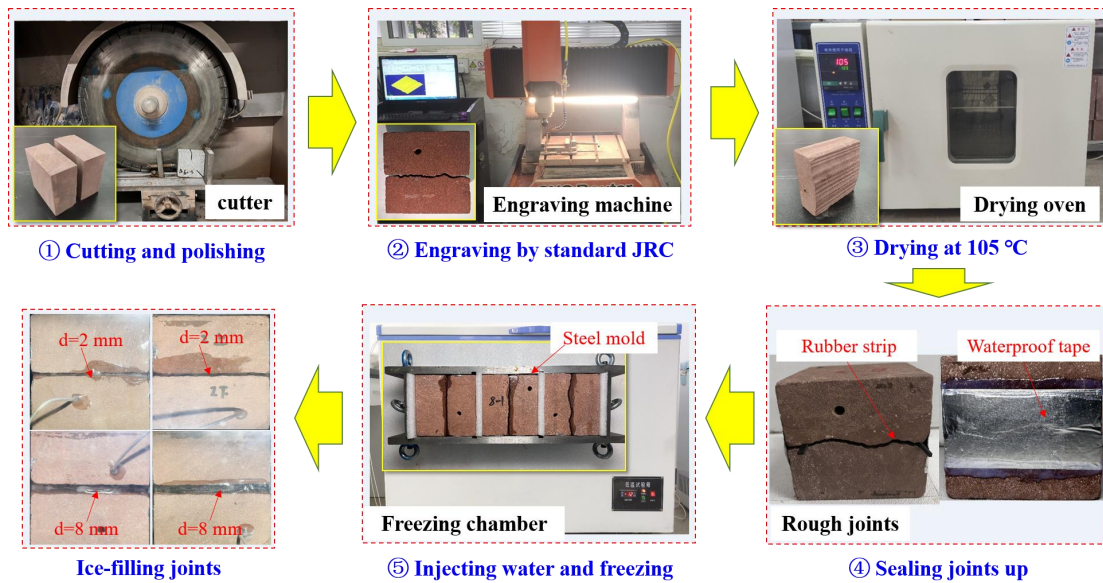

105 ⑤ When the waterproof tape was tightly bonded on the rock surface, liquid water should be injected  
106 into the artificial joint until no water leaks out. After that, the water-filled joint rock mass was put into  
107 a steel mold to freeze in a freezing chamber. The steel mold was used to control the joint opening  
108 because the volume of joint water would expand during freezing. Then ice-filled joint samples can be  
109 derived after freezing at -20 °C for 12 h. The manufacturing procedure and related ice-filled joint  
110 samples were shown in Fig. 1.

111 **Table 2.** Ten standard joint profiles (Barton and Choubey, 1977).

Profile No.	Typical roughness profiles	JRC range
No. 1		0-2 (0.4)
No. 2		2-4 (2.8)
No. 3		4-6 (5.8)
No. 4		6-8 (6.7)
No. 5		8-10 (9.5)
No. 6		10-12 (10.8)
No. 7		12-14 (12.8)

No. 8		14-16 (14.5)
No. 9		16-18 (16.7)
No. 10		18-20 (18.7)

113

114 **Figure 1.** Preparation of ice-filled joints. The preparation steps are as follows: ① Cutting and polishing, ②

115 Engraving by standard, ③ Drying at 105 °C, ④ Sealing joints up, ⑤ Injecting water and freezing.

116

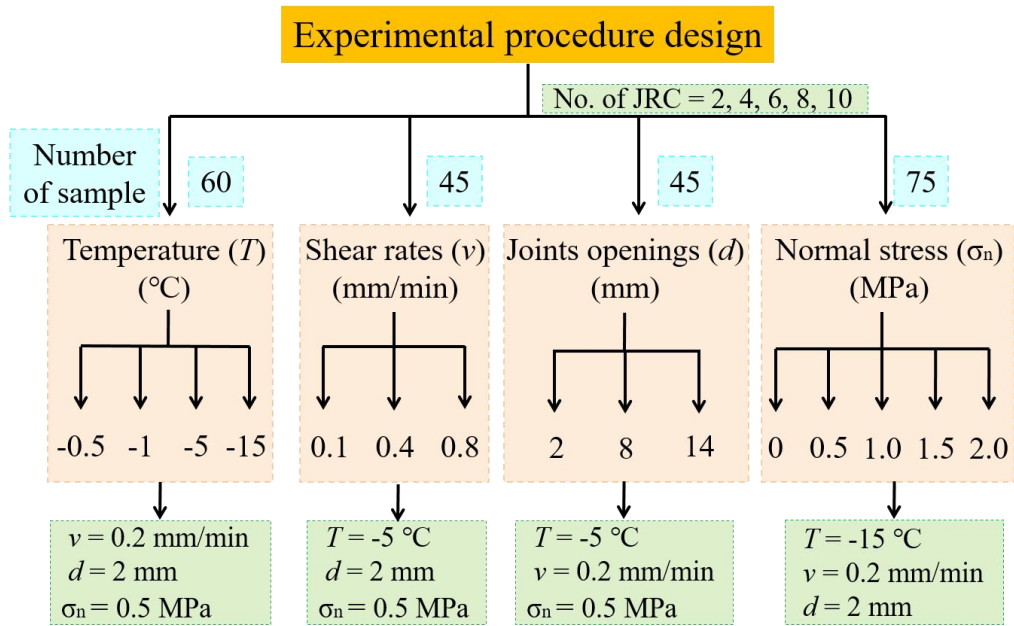

117 **Figure 2.** The shear directions for different joint profiles.

118 **2.3 Experimental procedures**

119 The main objective of this study is to investigate the effect of critical factors on the shear strength of  
 120 ice-filled joint rock mass, including the freezing temperature, joint roughness, shear rates, joint opening  
 121 and normal stress. The joint roughness is a basic index for rock joints, which is always considered  
 122 when investigating other factors. Therefore, all the samples can be divided into 4 groups, namely the  
 123 temperature group, shear rate group, joint opening group, and normal stress group. In the pre-test, the  
 124 shear strength of the ice-filled joint does not change when the temperature is below -5 °C, however, it  
 125 greatly decreases when the temperature increases from -5 °C to 0 °C. Therefore, the temperatures are  
 126 set as -15 °C, -5 °C, -1 °C and -0.5 °C, respectively. The shear rates are 0.2 mm/min, 0.4 mm/min and  
 127 0.8 mm/min in the shear rate group. In the joint opening group, the openings of ice-filled joints are 2

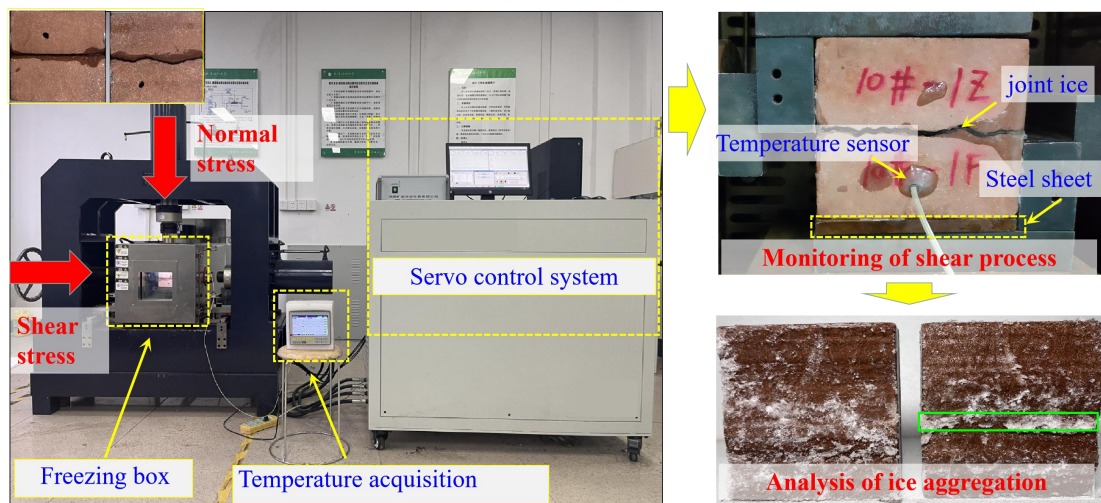

128 mm, 8 mm and 14 mm, respectively. The freezing depth on the earth may be small, however, it can  
129 exceed 100 m in some alpine caves, where the in-situ stress is close to 2 MPa. Therefore, in the normal  
130 stress group, the normal stresses are set as 0 MPa, 0.5 MPa, 1 MPa, 1.5 MPa and 2 MPa, respectively.  
131 Three parallel experiments were performed on each group to eliminate the discreteness of ice-filled  
132 joint samples and experiment error. There are approximately 225 ice-filled joint samples prepared in  
133 this experiment. The distribution of these ice-filled joint samples were shown in Fig. 3.  
134 All the water-containing joints were frozen in a freeze box at a specific temperature for about 12 h, and  
135 they were used to conduct the direct shear experiment on a temperature-controlled shearing instrument  
136 under the scheduled low temperature and normal stress (Fig. 4). A temperature sensor was implanted  
137 into the sample to accurately monitor the internal temperature change of ice-filled joint samples. In  
138 order to adjust the height of the ice-filled samples, a steel sheet was placed between the indenter and  
139 joint blocks. When the scheduled freezing temperature was reached, the normal stress was applied with  
140 a loading rate of 0.2 kN/s. Then the shear process was performed in the displacement mode with the  
141 designed shear rate. After the shear experiment, the rupture modes of ice-filled joints were captured  
142 and analyzed by using a camera.

148 **3 Experimental results**

149 **3.1 Effect of freezing temperature and joint roughness**

150 In the temperature group, freezing temperatures were set as -15 °C, -5 °C, -1 °C and -0.5 °C, and the  
151 joint roughness was named by the profile number in Table 2. The shear strength is dependent on the  
152 freezing temperature and joint roughness as shown in Fig. 5. The shear strength decreases remarkably  
153 with increasing freezing temperature. When the temperature increases from -15 °C to -0.5 °C, the mean  
154 strength decreases by approximately 54%, 32%, 60%, 46% and 56% for profiles of No. 2, No. 4, No. 6,  
155 No. 8 and No. 10, respectively. The shear strength of ice-filled joints does not always increase with  
156 JRC, which has a considerable reduction at the joint profiles of No. 6 and No. 10. It illustrates that solid  
157 ice is a kind of special infilled material, which is different from soft soils or cement-based materials  
158 (Xu et al. 2012; Zhao et al. 2020). The change trend of shear strength against JRC may be explained by  
159 the shear rupture mode, as shown in Fig. 6a. There are several aggregation regions of rupture ice close  
160 to large climbing bulges on the surface of joints. The peak shear strength of ice-filled joints is related to  
161 the aggregation area of rupture ice, because a large shear force is required to promote the solid ice to  
162 shear slide along the slope of bulges. It should be noted that the rupture ice has a white appearance, low  
163 transparency and obvious rupture characteristics by observing the enlarged pictures of the ice-filled  
164 joints after shear failure. Only the rupture ice before the noticeable bulges displays aggregation  
165 behavior. The area of the aggregation ice can be calculated after estimating the width of the  
166 aggregation ice from the pictures (Fig. 6b), because the joints are two-dimensional surfaces. This is a  
167 simple and approximate estimation method for the aggregation area of rupture ice.

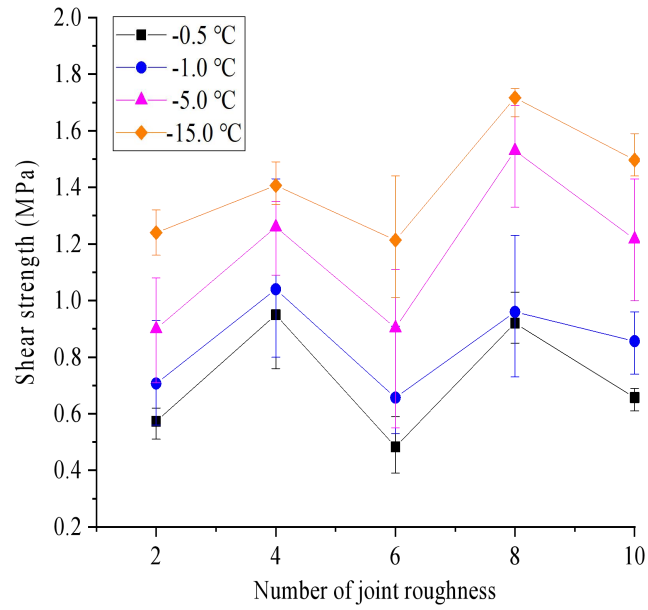

168 The accumulated aggregation area percentage of the rupture ice can be calculated as

$$A_i = \frac{\sum_{k=1}^n L_k}{L_{\text{joint}}} \times 100\% \quad (1)$$

170 where  $L_k$  is the width of the aggregation ice for the bulge  $k$ .  $L_{\text{joint}} = 10$  cm, which is the trace length of  
 171 the joint.

172 The aggregation area and location along the rough profile of joints after shear failure are plotted in Fig.  
 173 7. It can be observed that the aggregation ice appears before several high bulges and the aggregation  
 174 location is almost independent of the freezing temperature if aggregation ice occurs. The climbing  
 175 bulges in front of the aggregation ice are noticeable and influential. It implies that the influence of joint  
 176 roughness on the shear strengths of these ice-filled joints may be only controlled by several noticeable  
 177 bulges instead of the JRC index. Figure 8 shows that the shear strengths of No. 6 and No. 10 display  
 178 obvious reduction trends, which may be in accordance with the ice aggregation area. The ice  
 179 aggregation area decreases with increasing the freezing temperature, because the bonding strength  
 180 between ice and joint surface becomes to be weaker, and the shear rupture happens along the ice-rock  
 181 interface instead of solid ice when the freezing temperature is larger than  $-0.5$  °C.

182 In addition, when the freezing temperature is close to  $0$  °C, the pre-melting of ice-rock interface  
 183 induced by the normal stress will cause a reduction of bonding strength. Therefore, the shear strength  
 184 between bonded ice-rock interfaces is much smaller than the shear strength of solid ice at a high  
 185 freezing temperature close to the melting point of bulk ice, such as  $-0.5$  °C. It should be noted that the  
 186 aggregation phenomenon of rupture ice disappears when  $T = -0.5$  °C because the high-temperature ice  
 187 is ductile failure along the ice-rock interface instead of the joint ice itself. However, the climbing effect  
 188 still makes a significant contribution to the increase of shear strength.

189

190 **Figure 5.** Shear strength against joint roughness at different freezing temperatures. Experimental condition:  $\nu = 0.2$

204 **Figure 7.** Shear aggregation areas of ice along the profile of roughness. Experimental condition:  $v = 0.2$  mm/min,  
 205  $d = 2$  mm,  $\sigma_n = 0.5$  MPa. Some blue profiles (dotted curves) are located under the orange profiles (solid curves)  
 206 after shearing, which means the width of joints becomes smaller. Generally, the reduction of joint width occurs  
 207 before some bulges and the rupture ice will aggregate before these bulges. The bulges causing the reduction of  
 208 joint width and aggregation of ice are called noticeable bulges. The noticeable bulges have larger inclination angles  
 209 and they are far away from the joint edges.

210

211 **Figure 8.** Aggregation area of rupture ice increases with the reduction of freezing temperature. Experimental  
212 conditions:  $v = 0.2$  mm/min,  $d = 2$  mm,  $\sigma_n = 0.5$  MPa.  $A_i$ : aggregation area percentage of rupture ice.

213 The peak shear displacement and normal displacement also are dependent on the freezing temperature  
214 (Table 3 and Table 4). With the increase of freezing temperature, the peak shear displacement increases  
215 because the joint ice will change from brittle to ductile (Bragov et al., 2015). The brittle-ductile  
216 transition of pure ice also is related to the freezing temperature, and the rupture ice will be produced  
217 under the brittle failure condition. Lou et al. (2022) claimed that plain ice has strong brittleness at the  
218 temperature from  $-5$  °C to  $-20$  °C. The increasing aggregation area of the rupture ice in Fig. 6 further  
219 proves that the brittleness of ice increases with decreasing the freezing temperature. The maximum  
220 shear displacement before failure is smaller at  $-15$  °C, which may be caused by the high brittleness.  
221 When the temperature increases to  $-1$  °C, the solid ice becomes to be ductile, therefore a larger shear  
222 displacement arises before failure. However, the shear dilatancy reduces with increasing the freezing  
223 temperature. Solid ice is a kind of temperature-dependent material, the elastic modulus of which almost  
224 linearly decreases with increasing freezing temperature (Sinha, 1989; Han et al. 2016). The inhibition  
225 of normal stress on the shear dilatancy is greater at the high freezing temperature during the shear  
226 process.

227 Several typical shear stress-displacement and normal-shear displacement curves for the profile of No. 4  
228 are plotted in Fig. 9. The ice-filled joint shows significant residual shear strength beyond the peak point,  
229 which slightly decreases with increasing shear displacement. This residual shear strength is caused by  
230 the friction effect between the upper and lower ice-filled blocks. In addition, the normal shear dilatancy  
231 displays increasing trend with shear displacement, which is caused by the climbing effect of ice-filled

232 joints. It should be noted that the shear strength has a second rising point at the residual strength stage,  
 233 because the shear rate is increased from 0.2 mm/min to 1 mm/min in order to accelerate the completion  
 234 of the shear process. Schulson and Fortt (2012) claimed that the friction between ice interfaces  
 235 increases when the shear rates increase from 0.06 mm/min to 0.6 mm/min. Therefore, the sudden rise  
 236 of residual shear strength can be attributed to the accelerated shear rate.

237 **Table 3.** The peak shear displacement at the peak points of shear strength (mm)

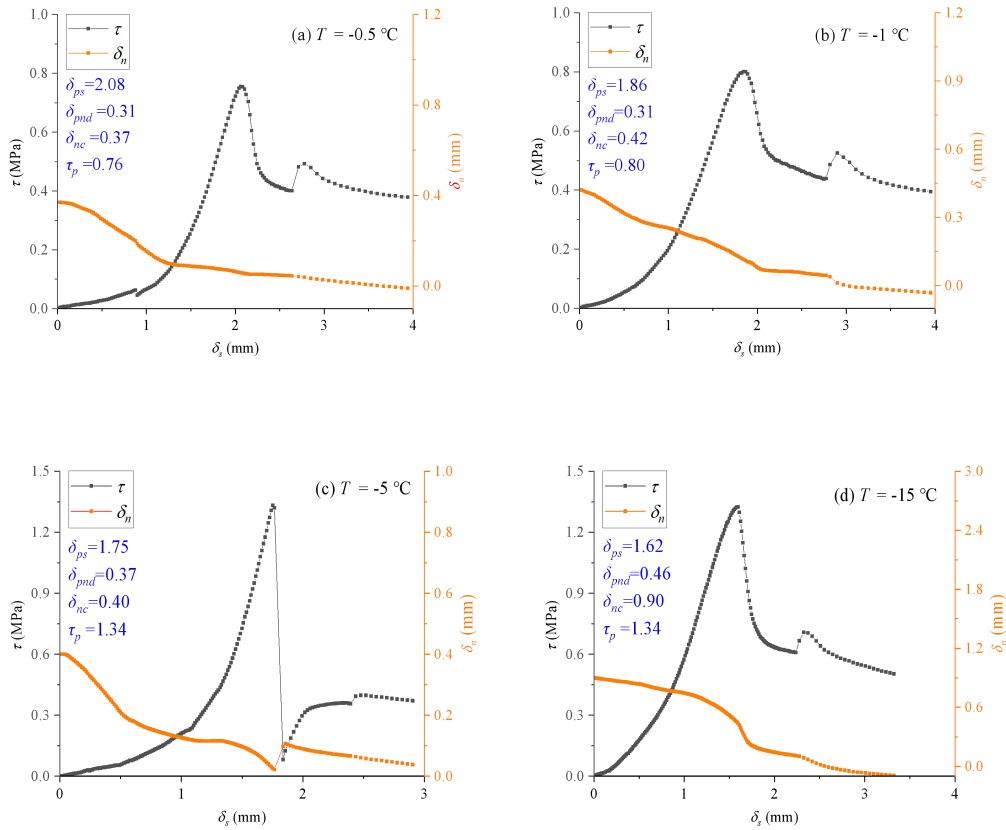

Profile No.	Freezing temperature			
	-15 °C	-5 °C	-1 °C	-0.5 °C
No. 2	1.36	1.46	1.72	1.84
No. 4	1.62	1.75	1.86	2.08
No. 6	1.33	1.53	1.71	1.83

No. 4	0.46	0.37	0.31	0.31
No. 6	0.27	0.28	0.22	0.12
No. 8	0.77	0.44	0.37	0.36

240

241

242

243 **Figure 9.** Shear strength and normal displacement versus the shear displacement for the profile of No. 4 in the  
 244 temperature group.  $\delta_{ps}$  and  $\delta_{pnd}$  are the shear displacement and normal shear dilatancy at the point of peak shear  
 245 strength,  $\tau_p$  and  $\delta_{nc}$  is the initial compression deformation.

246 Another finding is that the JRC is not suitable to interpret the influence of joint roughness on the shear  
 247 strength of ice-filled joints, because the peak shear strength does not monotonically increase with  
 248 increasing JRC index. The peak shear strength displays an increase-decrease-increase-decrease trend  
 249 against JRC from No. 2 to No. 10 (Fig. 5). Figure 10 shows that the peak shear strength displays a  
 250 linear increasing trend with increasing aggregation areas of fragmented ice after failure. The

251 aggregation area of fragmented ice can be treated as the effective climbing area which makes a  
 252 significant contribution to the improvement of shear strength, because the fragmented ice is produced  
 253 under compression-shear stress in the process of climbing the steep bulges. As a consequence, only  
 254 these steep bulges causing aggregation of rupture ice contribute to the improvement of shear strength.  
 255 The variation law of shear dilatancy against the roughness also is in accordance with the shear strength  
 256 of ice-filled joints, but it is different from the change law of JRC (Table 4). In Fig. 7, the gathering of  
 257 fragmented ice mainly arises in the front of the steepest bulge. It illustrates that the improvement of  
 258 shear strength of joint ice is caused by a part of the steepest bulge instead of the total roughness.  
 259 Therefore, JCR may be not suitable for the prediction of shear strength of ice-filled joints. For example,  
 260 although the JCR of No. 6 is much larger than No. 4, the effective steep bulge to cause ice aggregation  
 261 after failure is smaller than that of No. 4 (Fig. 8). This phenomenon confirms that the improvement of  
 262 shear strength is only caused by some noticeable steep bulges instead of the total bulges.

264 **Figure 10.** Peak shear strength linearly increases with increasing aggregation areas of rupture ice. Experimental  
265 condition:  $v = 0.2$  mm/min,  $d = 2$  mm and  $\sigma_n = 0.5$  MPa.

### 266 **3.2 Effect of shear rates**

267 The shear rates have significant effects on the strength of solid ice as observed in the previous literature  
268 (Petrovic, 2003). Low shear rates are used to conduct quasi-static shear experiments, including 0.2  
269 mm/min, 0.4 mm/min and 0.8 mm/min. Figure 11 shows that the peak shear strength slightly decreases  
270 with increasing shear rates. Solid ice is a kind of typical elasto-plastic material. When the shear rate is  
271 slow, the ice crystal has enough time to shear slip and it will present ductile failure characteristics. At a  
272 low shear rate, the free water on the slip interface will reorganize at the water-ice interface to form ice,  
273 however, it is hard for the ice crystal to adjust to adapt the shear slip at high shear rates, which will  
274 cause the shear rupture of ice crystals and hinder the growth of ice on the water-ice interface (Luo et al.,  
275 2019). Mamot et al. (2018) claimed that a high strain rate of  $10^{-3}$  s<sup>-1</sup> can induce brittle failure of ice and  
276 rock-ice contacts. At a lower shear rate, the stress concentration inside infilled ice can be relaxed and it  
277 changes to ductile creep deformation. Fukuzawa and Narita (1993) held that the brittle-ductile  
278 transition of ice under the shear process occurs around the strain rate of  $10^{-4}$  s<sup>-1</sup>. Here, the shear  
279 displacement rate is from 0.2 mm/min to 0.8 mm/min, corresponding to the strain rates from  $1.67 \times 10^{-3}$   
280 s<sup>-1</sup> to  $6.67 \times 10^{-3}$  s<sup>-1</sup>. Therefore, the shear rate in this study is very close to the threshold of brittle-ductile  
281 transition given in the previous literature. Figure 12 shows that a high shear rate will induce brittle  
282 failure of joint ice and more fragmented ice crystals are produced. As a result, the shear strength  
283 reduces with increasing shear rates from 0.2 mm/min to 0.8mm/min. In this study, the exact shear rate  
284 for the brittle and ductile transition of ice-filled joints is not accurately determined due to the limitation

285 of the shear rate range. More further shear experiments should be carried out on the ice and ice-filled  
286 joints by adopting a larger range of the shear rate.

287

288 **Figure 11.** Effect of shear rate on the peak shear strength. Experimental condition:  $T = -5$  °C,  $d = 2$  mm and  $\sigma_n =$

**Figure 12.** The shear rupture characteristics of joint ice under different shear rates. Experimental condition:  $T = -5\text{ }^{\circ}\text{C}$ ,  $d = 2\text{ mm}$  and  $\sigma_n = 0.5\text{ MPa}$ . The ice crystal that cannot adapt to shear slip at high shear rates will form brittle failure. The joint ice of brittle failure shows more micro fractures which make it more reflective. This will cause a white appearance of the rupture ice on the joint surface. The ductile failure of ice displays a transparent appearance without white color, which is hard to observe. Therefore, a larger area of white appearance implies a much more serious brittle failure of joint ice.

### 298 3.4 Effect of joint openings

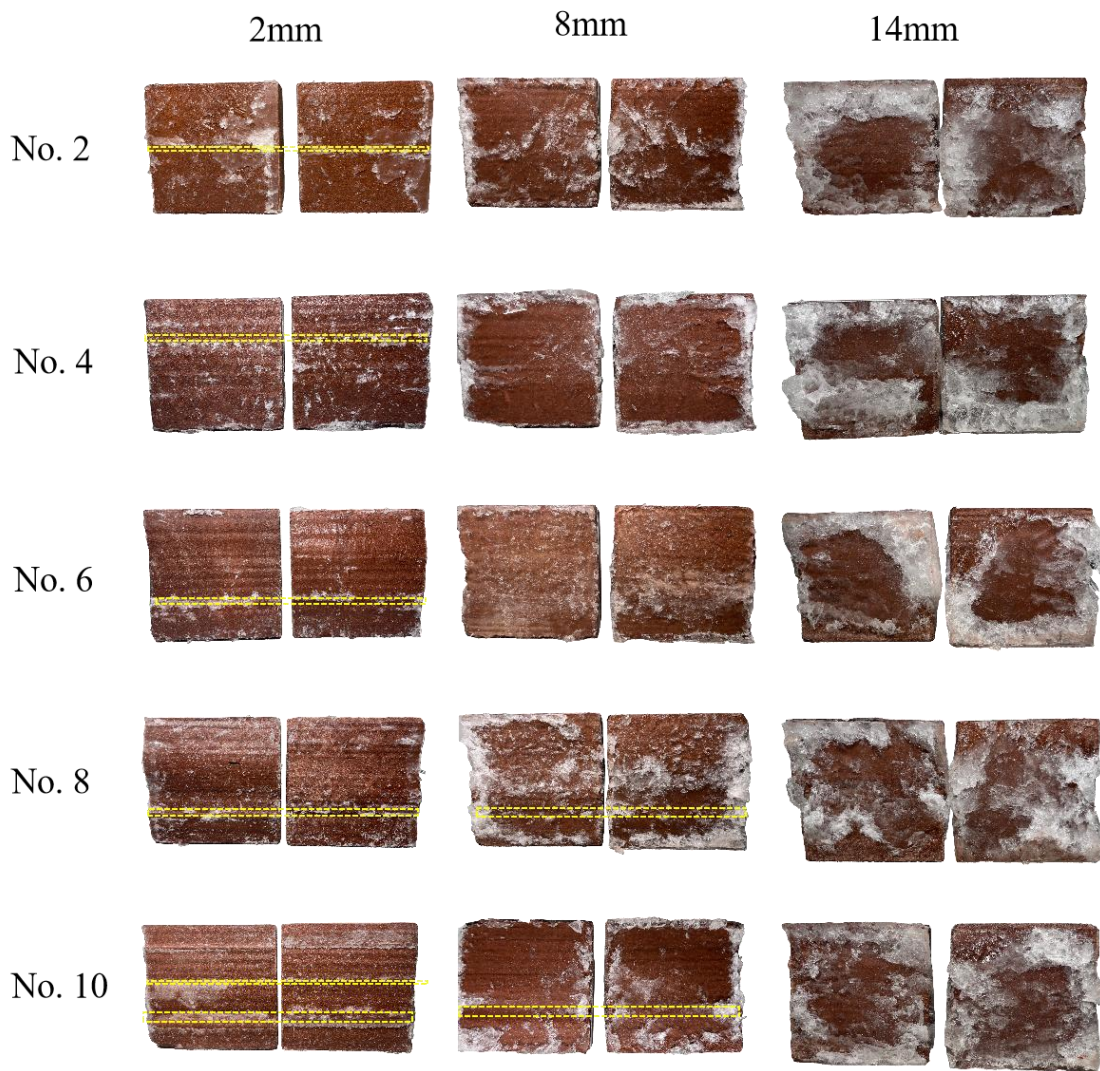

299 Joint opening is another critical factor influencing the shear strength of ice-filled joints, which is  
300 defined as the vertical distance between the upper and lower blocks. The standard JRC curves are  
301 suggested by Barton and Choubey (1977). We tested the maximum height difference of the standard  
302 JRC curves is approximately 2.14 mm, 2.40 mm, 6.24 mm, 6.85 mm and 4.48 mm for the profiles of  
303 No. 2, No. 4, No. 6, No. 8 and No. 10, respectively. The joint openings are chosen as 2 mm, 8 mm and  
304 14 mm, because 2 mm is smaller than all the maximum height differences while 14 mm is much larger  
305 than them. The rupture characteristics of joint ice against the joint opening are plotted in Fig. 13. When  
306 the joint opening is 2 mm, the aggregation phenomenon of rupture ice is evident. However, the  
307 aggregation phenomenon disappears for the profiles of No. 2, No. 4 and No. 6 when the joint opening  
308 is 8 mm. When the joint opening increases to 14 mm, there is not any aggregation of rupture ice arising  
309 for all the joints. Figure 14 shows that when the joint opening increases from 2 mm to 14 mm, the shear  
310 strength of ice-filled joints decreases. The shear strength of pure solid ice also is measured in the  
311 laboratory, which is approximately 0.83 MPa on the condition that  $T = -5\text{ }^{\circ}\text{C}$ ,  $v = 0.2\text{ mm/min}$  and  $\sigma_n =$   
312  $0.5\text{ MPa}$ . When the joint opening is 14 mm, the shear strengths of ice-filled joint are approximately  
313  $0.83\text{ MPa}$  and they are independent of the joint roughness. When the joint opening is 8 mm, the shear  
314 strengths of ice-filled joint are very close to the shear strength of pure solid ice ( $0.83\text{ MPa}$ ) for the joint  
315 of No. 2, No. 4 and No. 6. The reason is that 8 mm has exceeded the critical filling thickness of these  
316 joints (No. 2, No. 4 and No. 6), therefore the shear strength of these ice-filled joints is only controlled  
317 by the solid ice instead of joint roughness. In addition, there is not any significant ice aggregation on  
318 the joint surfaces of No. 2, No. 4 and No. 6 when the joint opening is 8 mm, and the shear failure

319 happens inside the joint ice. However, for the ice-filled joints of No. 8 and No. 10, the shear strengths  
320 are larger than 0.83 MPa, which illustrates that the critical filling thickness for the profiles of No. 8 and  
321 No. 10 should be larger than 8 mm but smaller than 14 mm. There is aggregation ice arising before  
322 large bulges, and these large bulges would prevent the direct shear failure of joint ice and improve the  
323 shear strength.

324 The influence of joint opening and roughness on the shear strength can be explained by using the shear  
325 failure path of ice-filled joints as shown in Fig. 15. When  $d=2$  mm, the shear climbing will occur before  
326 some large bulges for all the joint profiles. This climbing action induces the aggregation of rupture ice  
327 and change of shear path. As a consequence, the shear strength will improve. When  $d=8$  mm, the shear  
328 failure path will not be disturbed for the profiles of No. 2, No. 4 and No. 6, however, the shear failure  
329 path changes due to the climbing action for the profiles of No. 8 and No. 10, in which a significant  
330 aggregation of rupture ice is produced. Therefore, the shear strengths of ice-filled joints for the profiles  
331 of No. 2, No. 4 and No. 6 are approximately equal to the solid ice, while the shear strengths for the  
332 profiles of No. 8 and No. 10 are much larger than 0.83 MPa. When  $d = 14$  mm, the shear failure  
333 happens inside the joint ice for all joint profiles, therefore, the shear failure path and shear strength will  
334 not be influenced by the joint roughness and no aggregation of rupture ice occurs. The shear dilatancy  
335 deformation of the ice-filled joints in Fig. 16 has further proved the climbing actions, including all the  
336 profiles with joint opening of 2 mm, and the profiles of No. 8 and No. 10 with joint opening of 8 mm.  
337 The climbing effect of the No. 2 ice-filled joint with opening of 2 mm is not remarkable, therefore the  
338 shear dilatancy is very small and the shear strength also is close to pure solid ice (0.83 MPa).  
339 Regardless of the critical filling thickness, the present study shows that the shear strength of ice-filled

340 joints decreases with increasing joint openings from 2 mm to 14 mm, and it is related to the joint  
 341 roughness below the critical infilled thickness. When the filling ice exceeds the critical thickness, the  
 342 shear strength of ice-filled joints is equal to the shear strength of solid ice under the same condition. It  
 343 should be noted that the critical filling thickness for each roughness will be determined in future  
 344 studies.

346 **Figure 13.** The shear rupture characteristics of ice-filled joints with different openings. Experimental condition:  $T$   
 347  $= -5\text{ }^{\circ}\text{C}$ ,  $d = 2\text{ mm}$  and  $\sigma_n = 0.5\text{ MPa}$ . The yellow lines show the main aggregation of rupture ice. Ice after rupture  
 348 will aggregate in roughness bulges perpendicular to the shear direction. The aggregation phenomenon disappears

349 as the joint openings increase. The aggregation phenomenon of profiles No. 2, No. 4 and No. 6 disappear in 8 mm

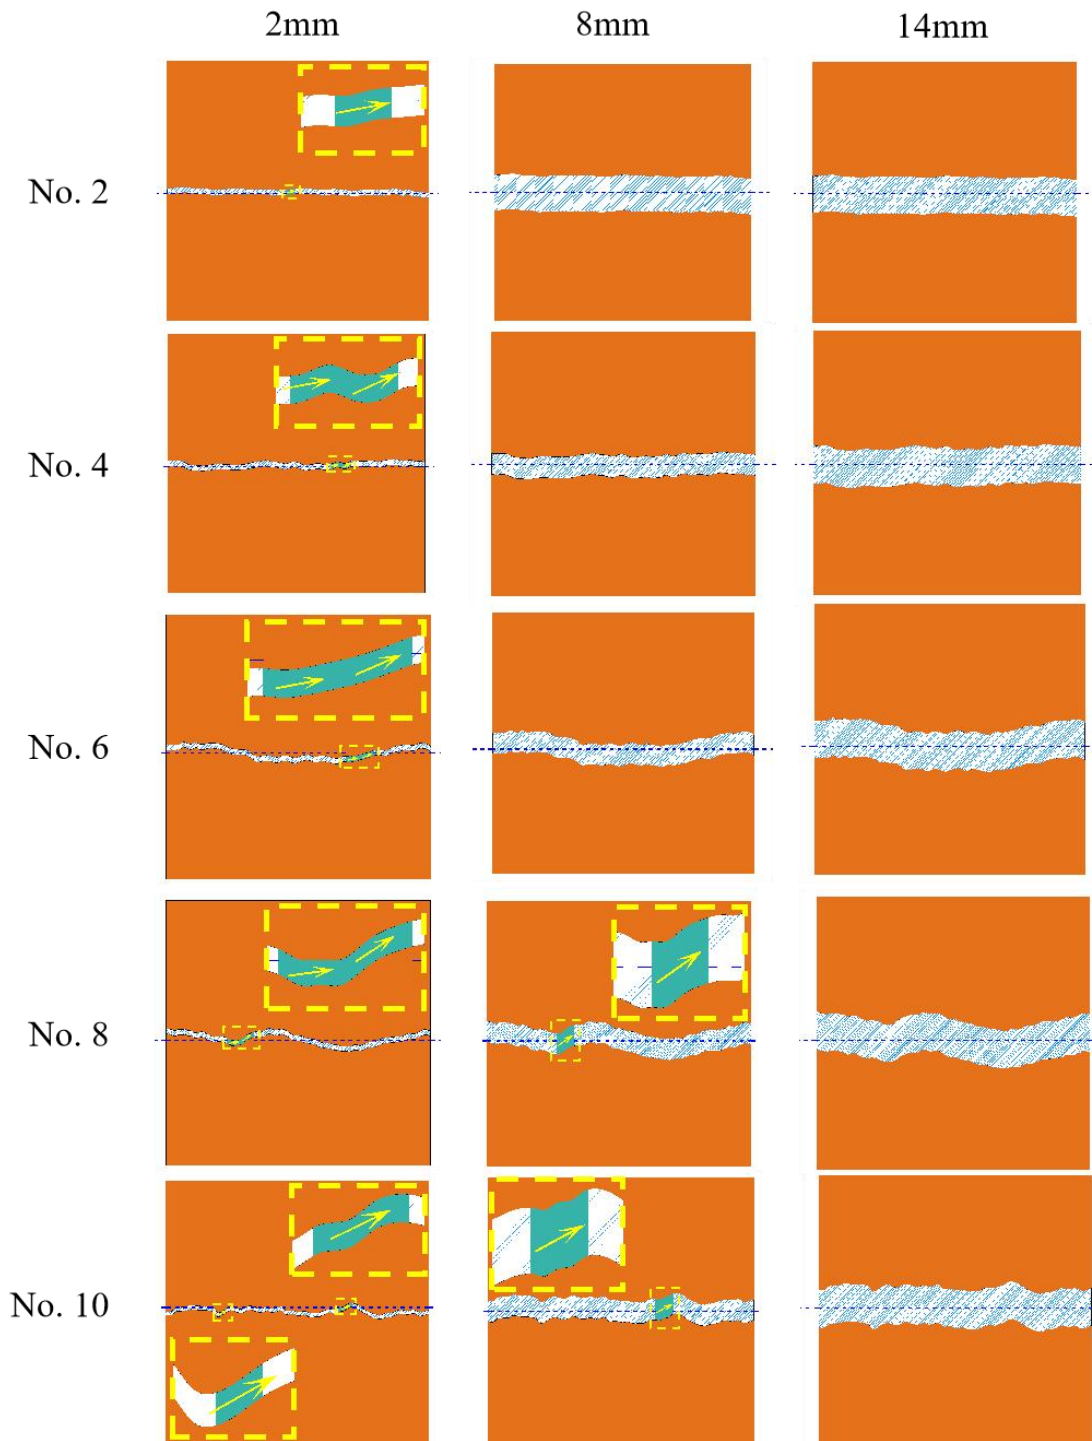

350 joint openings. All profiles' aggregation phenomena disappear in 14 mm joint openings.

351

360 and  $\sigma_n = 0.5\text{ MPa}$ .

### 361 3.5 Effect of normal stress

362 The normal stress group was used to investigate the effect of normal stress on the shear strength of

363 ice-filled joints, including 0 MPa, 0.5 MPa, 1.0 MPa, 1.5 MPa and 2.0 MPa. The shear strength of

364 ice-filled joints displays a significant increasing trend with increasing normal stress (Fig. 17). The

365 Mohr-coulomb criterion may be used to express the relationship between the shear strength and normal

366 stress as below:

$$367 \tau_p = c_j + \sigma_n \tan \phi_j \quad (2)$$

368 where  $\tau_p$  = shear stress on plane,  $\sigma_n$  = normal stress on plane,  $c_j$  = cohesion of ice-filled joints,

369  $\phi_j$  = internal friction angle of ice-filled joints.

370 Figure 17 shows Mohr-coulomb criterion can be well used to calculate the shear strength of ice-filled

371 joints against the normal stress. The shear rupture modes of the joint ice are given in Fig. 18. A

372 remarkable ice aggregation phenomenon can be found on the surface of joints and the aggregation  
 373 occurs at a stable location of the joint profile regardless of the normal stress. The aggregation area of  
 374 rupture ice increases with increasing normal stress, because climbing bulges is harder and the solid ice  
 375 is easier to be crush at the front of large bulges under the higher normal stress (Fig. 19). In Section 3.1,  
 376 it has illustrated that the aggregation area of rupture ice is an important index to reflect the shear  
 377 strength of ice-filled joints at different freezing temperatures. Actually, the shear strength also linearly  
 378 increases with increasing the aggregation area of rupture ice under different normal stress as shown in  
 379 Fig. 20. It further illustrates that only some large bulges causing the aggregation of rupture ice can  
 380 contribute to the improvement of shear strength instead of the total roughness index, such as JRC.

#### 397 4. Discussion

##### 398 4.1 The warming degradation mechanism of ice-filled joints

399 In this paper, the influence of freezing temperature, shear rate, joint opening and normal stress on the

400 shear strength of ice-filled joints in rock masses was comprehensively investigated by experiments. The

401 shear strength remarkably reduces with increasing freezing temperature, because the shear strengths of

402 solid ice and ice-rock interface decrease with increasing temperature. In order to deeply understand the

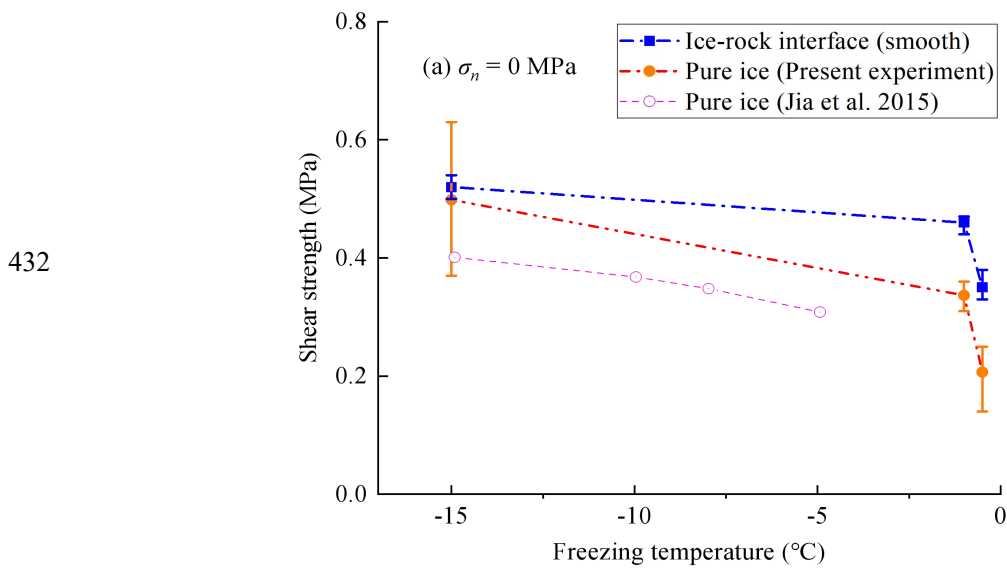

403 warming degradation mechanism of ice-filled joints, the shear strength of pure ice and ice-rock

404 bonding interface under different freezing temperatures also were tested in this study (Fig. 21).

405 The test results show that the shear strength of smooth ice-rock bonding interface is larger than that of  
406 pure solid ice at the freezing temperature from -15 to -0.5 °C (Fig. 21a). It implies that the shear failure  
407 should be inside the solid ice instead of ice-rock interface. When the freezing temperature increase  
408 from -1 °C to -0.5 °C, the shear strengths of the ice-rock interface and the solid ice reduce very quickly.  
409 Jia et al. (2015) also claimed the same change law of solid ice against the temperature.

410 However, the experimental results show that the shearing failure of many rough ice-filled joints at  
411 -0.5 °C is the debonding of ice-rock interfaces (Figs. 6, 12, 13, 18). More shear experiments were  
412 carried out on rough ice-rock interfaces with profiles of No. 4 and No. 8 on the same experimental  
413 condition ( $\sigma_n = 0.5$  MPa,  $v = 0.2$  mm/min). It shows that the shear strength of rock-ice-rock “sandwich”  
414 is a little larger than that of ice-rock interface, although the change laws of them against temperature  
415 are very similar. Another novel finding is that the shear strength of ice-rock interface is larger than the  
416 shear strength of solid ice itself below -1 °C (Fig. 21b). Therefore, the shear failure below -1 °C  
417 displays the cracking of joint ice instead of ice-rock interface, and some aggregation areas of rupture  
418 ice occur before large bulges (Figs. 6, 12, 13, 18). However, the shear strength of solid ice is larger  
419 than that of ice-rock interface above -1 °C. This is the main reason for the shear failure of rough  
420 ice-filled joints along ice-rock interfaces at -0.5 °C. The freezing temperature of -1 °C is the transition  
421 point of shear failure modes. Figure 22 presents that the shear failure is along the ice-rock interface  
422 when the freezing temperature is approximate -0.5 °C, however, the area of ice attached to the joints  
423 has a great increment with the decrement of freezing temperature from -0.5 °C to -15 °C. It further  
424 illustrates that the shear strength of rough ice-rock interface is larger than that of the solid ice below  
425 -5°C. Mamot et al. (2018) also found that the shear failure modes of the smooth ice-filled joints

426 changed from shearing cracking of joint ice to the debonding of ice-rock interface when the freezing  
427 temperatures increased from -10 °C to -0.5 °C. The smooth joints have a little ability to resist the shear  
428 slide of ice-filled joints. Mamot et al. (2018) claimed that three shear failure modes may arise between  
429 -5 °C to -1 °C, including the debonding of ice-rock interface, shear cracking of joint ice and their mixed  
430 mode. However, only the shear cracking of joint ice occurs at -5 °C to -1 °C in this study. Therefore,  
431 the joint roughness has an effect on the shear strength of ice-filled joints and the shear failure modes.

433

434 **Figure 21.** Influence of freezing temperature on the direct shear strength of ice and ice-filled joints. Experimental  
 435 condition:  $\nu = 0.2$  mm/min.

436

437 **Figure 22.** Shear failure characteristics of ice-rock interfaces under different temperatures. Experimental condition:  
 438  $\nu = 0.2$  mm/min,  $\sigma_n = 0.5$  MPa.

439

#### 440 **4.2 The coupled effect of joint roughness, opening and normal stress**

441 The shear strength of smooth ice-filled joints were investigated by Mamot et al. (2018). They found  
442 that the shear strength of smooth ice-filled joints also linearly increases with decreasing temperatures.  
443 Actually, the roughness is another important factor influencing the shear strength of ice-filled joints,  
444 which can improve the ability to resist the shear slide of joints (Fig. 23). The shear strength of the No. 2  
445 ice-filled joint is much smaller than that of No. 8 and No. 10 joints. For the profile of No. 2, the shear  
446 strength of ice-filled joint is approximately equal to that of the solid ice when the normal stress is less  
447 than 1.5 MPa, because the joint opening of 2 mm also is very close to the maximum height difference.  
448 Therefore, the joint opening will determine the effect of joint roughness. However, the shear strength of  
449 solid ice is much smaller compared with the shear strength of ice-filled joints when the normal stress is  
450 2 MPa. It is observed that this normal stress has caused some vertical micro-cracks inside the solid ice.  
451 For the ice-filled joints, the compression damage maybe not remarkable, because both the adhesion of  
452 ice-rock interface and bulges will prevent the lateral expansion of solid ice under high normal stress. A  
453 larger roughness may provide a much stronger confining effect on the lateral expansion. Although the  
454 shear strength increases with increasing JRC number in general, the quantitative relationship between  
455 them are hard to determine. Figure 5 shows that the change of shear strength against the JRC number is  
456 fluctuating. A novel finding of this study is that the aggregation area of rupture ice before large bulges  
457 can be well used to predict the shear strength of ice-filled joints. However, it should be noted that a  
458 new index of roughness should be proposed in future research in order to build the shear strength  
459 model considering joint roughness.

460 In addition, if the joint opening exceeds the critical value, the influence of joint roughness on the shear  
 461 strength of ice-filled joints will disappear. For example, when the thickness of joint ice exceeds 14 mm,  
 462 the shear strength of all the ice-filled joints is equal to the shear strength of infilled ice. Section 3.4 has  
 463 illustrated that the value of critical joint opening is depended on the maximum height different of the  
 464 joint, which need to study further.

465  
 466 **Figure 23.** Shear failure characteristics of ice-rock interfaces under different normal stress. Experimental condition:  
 467  $v = 0.2\text{mm/min}$ ,  $d = 2\text{ mm}$ ,  $T = -15\text{ }^\circ\text{C}$ .

468  
 469 **4.3 Potential application for prediction of rock avalanches in a warming climate**

470 In recent years, there are many large rock avalanches occurred in the Alps. The rock avalanches that  
 471 occurred on the Brenva galcier, the Punta Thurwieser and the Drus are some of the recent examples,  
 472 which have strong impacts on the high mountain infrastructure stability and landscape evolution  
 473 (Mamot et al., 2018). The rock avalanches are related to the degradation of bedrock permafrost and

474 ice-filled joints. Our study shows that the peak shear strength of ice-filled joints increases with the  
475 increase of roughness and normal pressure. This implies that the rockfall will be more stable with  
476 higher roughness and normal pressure. In addition, when the joint openings increase, the peak shear  
477 strength will decrease, and large joint openings will reduce the effect of joint roughness. The peak  
478 shear strength of ice-filled joints decreases with the increase of freezing temperature. Moreover, when  
479 the freezing temperature is close to 0 °C, the pre-melting of ice-rock interface induced by the normal  
480 stress will cause a reduction of bonding strength. This result can explain the phenomenon that the  
481 boundary of ice-filled joint between frozen and unfrozen become unstable, especially in summer. The  
482 peak shear strength of ice-filled joints decreases with the increase of shear rate. It is hard for the ice  
483 crystal to adjust to adapt the shear slip at high shear rates so the rockfall may happen.

484 As the global temperature rises, collapse disasters of ice-filled rock mass caused by warming and  
485 thawing often occur in permafrost regions. A constitutive model can be further constructed according  
486 to the experiment results. Then combining with a numerical software, this constitutive model can be  
487 used to predict the disaster of rock avalanches in the cold region in the future research. Although  
488 Mamot et al. (2018) has established a constitutive model for joints, the constitutive model only  
489 considers temperature and normal stress, however, the influence of the joint roughness, opening and  
490 shear rate is ignored. Through our study, it is evidenced that the joint roughness, shear rate, joint  
491 opening and temperature are physical quantities that must be considered in the constitutive model. A  
492 constitutive model including these physical quantities will be proposed in our future research.

## 493 **5 Conclusions**

494 The following conclusions can be obtained in this study:

495 (1) The shear strength of ice-filled joints decreases with increasing temperature. The shear failure mode  
496 change from shear rupture of joint ice to the debonding of ice-rock interface when the temperature  
497 increases to  $-0.5\text{ }^{\circ}\text{C}$ , because the bonding strength of ice-rock interface is less than that of solid ice at  
498  $-0.5\text{ }^{\circ}\text{C}$  ( $v = 0.2\text{mm/min}$ ,  $\sigma_n = 0.5\text{ MPa}$ ).

499 (2) The joint roughness can improve the shear strength of ice-filled joints, but it is related to the joint  
500 opening and normal stress. The shear strength of ice-filled joints linearly increases with increasing the  
501 aggregation area of rupture ice before noticeable bulges. However, the relationship between the JRC  
502 index and the shear strength is not significant.

503 (3) The shear strength of ice-filled joints decreases with increasing joint opening. When the joint  
504 opening increases from 2 mm to 14 mm, the aggregation of rupture ice gradually disappears and the  
505 shear strength of ice-filled joint is equal to that of solid ice. A critical value of infilled thickness may  
506 exist, which need further study.

507 (4) The shear strength of ice-filled joints decreases when the shear rate increase from 0.2 mm/min to  
508 0.8 mm/min. The infilled ice may change from ductile to brittle failure with increasing shear rate. The  
509 aggregation area of rupture ice also decreases while the brittle rupture phenomenon of joint ice is more  
510 obvious as the shear rate increases.

511 (5) The shear strength of ice-filled joints linearly increases with increasing normal stress, which well  
512 satisfies the Mohr-coulomb criterion. The aggregation area of rupture ice also increases with increasing  
513 normal stress. In addition, the improvement of shear strength caused by the normal stress is much  
514 larger for the ice-filled joints than the solid ice, because the bulges can prevent the lateral expansion of  
515 ice under compression.
