Abstract. The supraglacial drainage system of the Greenland Ice Sheet, in combination with surface melt rate, controls the rate of water flow into moulins, a major driver of subglacial water pressure. We apply SaDS, a physically-based surface meltwater flow model, to a $\sim 20 \times 27 \text{ km}^2$ catchment on the southwestern Greenland Ice Sheet for four years of melt forcing (2011, 2012, 2015, and 2016) to examine the relationship between surface melt rate and the rate, diurnal amplitude, and timing of surface inputs to moulins, to compare SaDS to contemporary models, and to present a framework for selecting appropriate supraglacial drainage models for different modelling objectives. We find that the extent to which surface melt rate controls moulin inputs is proportional to annually integrated surface melt volume, and that variations in the rate and timing of modelled moulin inputs related to the development of supraglacial channels are relatively more important in years with low melt volumes than years with high melt volumes. We suggest that a process-resolving supraglacial hydrology model (e.g., SaDS) should be considered when modelling outcomes are sensitive to sub-diurnal and long-term seasonal changes in the rate of discharge into moulins.

1 Introduction

The supraglacial drainage system acts as a mediator in the relationship between surface melt and subglacial water pressure (e.g., Bartholomew et al., 2012; Sole et al., 2013; Andrews et al., 2014) since meltwater generated at the surface must first flow through supraglacial catchments before being transported through the depth of the ice via moulins and crevasses. Since supraglacial drainage in part controls the form of inputs to moulins, it has the potential to significantly affect the relationship between surface melt and ice velocity (e.g. Banwell et al., 2016).

Water flow through the supraglacial drainage system is understood to occur through both distributed, or hillslope/interfluvial, drainage (e.g. Pitcher and Smith, 2019), and through discrete supraglacial channels. The density of supraglacial channels (which we refer to as “drainage density”) is a key control on the amplitude and timing of moulin inputs, since transport through channels is more efficient than through distributed drainage (Yang et al., 2018; Pitcher and Smith, 2019; Yang et al., 2022). The evolution of drainage density is controlled by processes including downward incision of supraglacial streams by frictional potential energy dissipation and shortwave radiation penetration (Pitcher and Smith, 2019), aspect-dependent erosion of exposed channel walls (St Germain and Moorman, 2019), and ablation of the ice surface according to the local energy balance (St Germain and Moorman (2019)). Supraglacial drainage is made more complex by supraglacial lakes, which form in topographic

25 depressions and may drain by slow overtopping once the lake level reaches the minimum outlet elevation (e.g., Chudley et al., 2019), rapid incision of outlet channels (e.g., Kingslake et al., 2015), or rapidly through hydrofracture at the lake bed (e.g., Das et al., 2008).

Supraglacial drainage characteristically acts to reduce the diurnal amplitude and delay the timing of moulin inputs relative to the diurnal cycle of surface melt (e.g., Smith et al., 2017; Muthyala et al., 2022). This behaviour has previously been captured
30 by supraglacial water flow models based on explicit flow routing and cascading supraglacial lake filling (Banwell et al., 2012; Koziol and Arnold, 2018), the transient filling of supraglacial lakes (Leeson et al., 2012), and flow through predefined channel networks (Yang et al., 2018; Gleason et al., 2021; Yang et al., 2022).

Each of these models makes a tradeoff between process representation and computational cost. Here, we apply the physics-based Subaerial Drainage System (SaDS) model, which aims to include a wide variety of processes (at the expense of compu-
35 tational efficiency), including the seasonal evolution of drainage density (Hill and Dow, 2021). The process-based formulation results in dynamic moulin inputs that are driven by changes in surface melt rate and previous melt conditions through the configuration of incised supraglacial channels.

We use SaDS to investigate the behaviour of modelled supraglacial drainage in southwest Greenland in order to: (1) explore the impacts of seasonally and annually varying melt volumes on moulin input rates, (2) compare SaDS to a suite of contempo-
40 rary models, and (3) provide suggestions about how to select appropriate supraglacial drainage models for different modelling objectives.

2 Data and Methods

2.1 Study Site

We model meltwater flow across a $\sim 20 \times 27 \text{ km}^2$ portion of the southwestern Greenland Ice Sheet, centered on 67.639°N ,
45 48.960°W (Fig. 1). The site contains seven internally drained supraglacial catchments varying in surface area from $<1 \text{ km}^2$ to $>100 \text{ km}^2$ (Table 1). The surface elevation of the modelled domain ranges from approximately 1150 m to 1450 m, and the area falls entirely within the bare-ice ablation zone. This area has been the site of previous supraglacial hydrology mapping (Yang and Smith, 2016) and modelling (Hill and Dow, 2021), which have shown that an extensive system of meltwater channels and lakes forms each summer. The four largest lakes in the domain are labelled L1 to L4, and range in elevation from 1215 m to
50 1387 m and in maximum modelled surface area from 0.45 km^2 to 1.39 km^2 (Table 1). These lakes are small to average size for this portion of western Greenland, e.g. Johansson et al. (2013) report median lake sizes between 1.41 to 2.12 km^2 for west Greenland.

2.2 Model

We model water flow across the domain and meltwater inputs to moulins using the Subaerial Drainage System (SaDS) model
55 (Hill and Dow, 2021). SaDS is a physics-based model that combines distributed hillslope flow with channelized flow in discrete

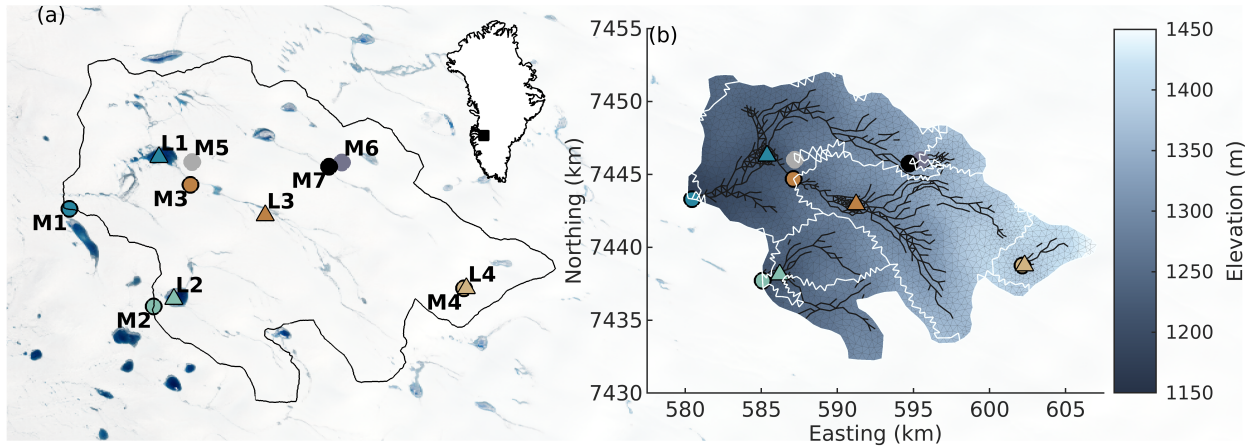

Figure 1. (a) Study domain with moulin locations (circles) previously mapped from a Landsat 8 image (Yang and Smith, 2016) and the four largest supraglacial lakes (triangles; L1–L4). Moulins indicated with a black outline (M1–M4) drain one of the four labelled supraglacial lakes. Background image is a Landsat 8 scene from 8 July 2021. Inset shows location of study site within the Greenland Ice Sheet. (b) Model domain with surface elevation derived from 32 m-resolution ArcticDEM mosaic data (Porter et al., 2018), modelled supraglacial channel network (black line segments), computational mesh (thin black triangles), and supraglacial sub-catchments for each moulin (white lines). Moulins (circles) and lakes (triangles) are as in (a). Coordinates are in UTM 22N projection.

Table 1. Catchment characteristics and catchment-averaged melt rates for the seven sub-catchments identified in Fig. 1). For catchments 1–4 that contain labelled supraglacial lakes, lake area and lake elevation are computed from modelled water depth fields. Catchments 5–7 do not contain labelled supraglacial lakes.

Catchment	Lake Area (km ²)	Lake Elevation (m asl)	Catchment Area (km ²)	Mean elevation (m asl)	Mean melt (m w.e.)			
					2011	2012	2015	2016
1	1.39	1215	102.1	1258	2.39	2.71	1.28	2.44
2	0.45	1218	27.8	1264	2.40	2.73	1.24	2.49
3	1.04	1276	94.4	1335	2.05	2.41	1.00	2.06
4	0.49	1387	18.8	1408	1.66	2.02	0.82	1.57
5	N/A	N/A	1.70	1278	2.34	2.67	1.22	2.41
6	N/A	N/A	7.73	1366	1.95	2.35	0.92	1.96
7	N/A	N/A	0.73	1345	2.08	2.46	0.99	2.11

supraglacial streams. Since the flow velocity is dictated by the hydraulic potential of the water surface, lakes naturally form in topographic depressions (e.g., Leeson et al., 2012). The model explicitly computes changes to supraglacial stream cross-section area and channel network capacity based on the balance between stream incision by frictional melt along the wetted perimeter and ablation of the adjacent ice surface in order to capture seasonal changes in moulin inputs. Flow is exchanged

60 between the distributed and channelized drainage systems through an explicit mass exchange term that is proportional to the hydraulic potential difference between the two systems. The model is posed on an unstructured triangular mesh, with hillslope flow across elements, channelized flow on edges, and moulins on nodes. The primary model outputs are the rate of supraglacial discharge into moulins, the water depth in supraglacial channels and in the distributed system, and the incised cross-sectional area of supraglacial channels. For more details about the model, refer to Appendix A and Hill and Dow (2021). To apply SaDS
65 to our domain, we use a mesh with 1984 nodes, 3768 elements, 5751 edges, a maximum element area of 0.15 km^2 , and a minimum area of 0.015 km^2 (Fig. 1).

2.3 Data

Surface elevations of each element in our triangular numerical mesh are computed from ArcticDEM 32 m-resolution mosaic data (Porter et al., 2018). We first smooth the ArcticDEM with a moving average filter with an edge length of 1.44 km, and
70 then average the pixels that lie within each triangular element to define the centroid elevation.

Moulin locations are adjusted from the Landsat-derived map of Yang and Smith (2016) to correct for potential discrepancy in in-situ flow routing between the acquisition time of the Landsat scene used to map hydrology features (19 August 2013; Yang and Smith, 2016) and the acquisition time of ArcticDEM (2011–2017; Porter et al., 2018). Some evidence of this type of discrepancy is provided by our sub-catchment boundaries in Fig. 1b that don't all extend to the domain boundary, which
75 instead follows the catchment boundaries from Yang and Smith (2016).

Surface melt is computed for our domain from RACMO2.3p2 surface melt data at 5.5 km horizontal resolution and 3 hour temporal resolution (Noël et al., 2019). Melt rates from RACMO tiles are interpolated in time and linearly interpolated in space to the triangular mesh and to run the model with a timestep of 20 s. Based on tests applying RACMO melt with linear and piecewise cubic modified Akima interpolation (Akima, 1970) (implemented with the MATLAB option 'makima'), the
80 discrepancy in the timing of peak moulin inputs is <0.5 hours and the discrepancy in the magnitude of peak moulin inputs is $\sim 1\%$ between linear and Akima interpolation (Fig. B1). Therefore, since the model outputs are only weakly sensitive to the interpolation scheme, and since we don't have information on how melt rate varies on timescales shorter than the RACMO timestep (3 hours), we use the simplest numerically feasible option and linearly interpolate melt rates in time. We model the years 2011, 2012, 2015, and 2016 to explore how the duration, intensity, and variability of surface melt impact the supraglacial
85 drainage system.

2.4 Model initialization

In all years, SaDS is initialized with zero water depth across the supraglacial drainage system and with a bare-ice surface. This initialization neglects the impact of early season snow cover and interannual water storage in supraglacial lakes (Law et al., 2020) on moulin inputs. While seasonal snow cover persists, surface meltwater should be retained within the snowpack, with
90 lateral transport occurring within saturated layers within the snowpack (e.g., Colbeck, 1974), therefore delaying early season moulin inputs. A physics-based snowpack and firn model (e.g. Meyer and Hewitt, 2017) is an attractive candidate to combine with SaDS. Such a model would allow SaDS to be applied across a larger elevation range and more robustly in the early melt

season. However, since this type of snow model would further increase the computational cost and significantly complicate the input data requirements of SaDS, this coupling is not pursued here.

95 The depth and location of supraglacial channels is spun up using the melt year in our series with average total surface melt (2013) to naturally form an initial channel network. This channel configuration is used as the initial condition for channel depth for 2011 and 2015. The channel depth from the end of 2011 and 2015 are used as initial conditions for 2012 and 2016, respectively. We expect that incorporating memory of past melt seasons in this way is key to capturing important interannual changes in moulin inputs (Hill and Dow, 2021).

100 3 Results

From model outputs for 2011, 2012, 2015, and 2016, we extract the rate of surface inputs to moulins (Fig. 2), the relative diurnal amplitude of inputs to moulins (measured as the peak-to-peak range in moulin inputs, normalized by the average moulin input) (Fig. 3), the lag time between local solar noon ($\sim 15:22$) and peak moulin inputs (Fig. 4), and the water depth in the four largest supraglacial lakes (Fig. 5).

105 For all seven catchments, moulin inputs generally track surface melt rate (Fig. 2), but with diminished diurnal amplitude (Fig. 3) and a phase lag of ~ 2 to ~ 8 hours (Fig. 4e, f). In all four years, the rate of surface inputs to moulins is closely tied to surface melt rate (Fig. 2), with a range of 0 to $\sim 70 \text{ m}^3 \text{ s}^{-1}$ depending on catchment size and surface melt rate (Table 1).

The relative diurnal amplitude of moulin inputs varies between $\sim 15\%$ and $>90\%$. The diurnal amplitude shows some sensitivity to surface melt rate (Fig. 3). For example, the relative diurnal amplitude for the highest melt year (e.g., 10–30% for 110 M1–M4 in mid-July 2012 with surface melt rate $>0.07 \text{ m w.e. day}^{-1}$) is typically less than for the lowest melt year (e.g., $>30\text{--}60\%$ for M1–M4 in July 2015 with surface melt $<0.06 \text{ m w.e. day}^{-1}$).

Peak moulin input rates lag behind solar noon by ~ 2.5 to 7.5 hours. The time lag does not show clear trends with volume of surface melt rate, since a similar magnitude and range of lag time is observed in all years (Fig. 4). However, the lag time appears sensitive to rate of change of surface melt rate, with the highest lag times observed during transient peak melt events, 115 especially with melt greater than $0.04 \text{ m w.e. day}^{-1}$ (e.g., July 2011, July 2012, June 2016).

The four labelled supraglacial lakes fill quickly in the early melt season. Once the lakes have filled (the storage volume in the absence of surface melt can be approximated by the lake depth at the end of the melt season), lake depth remains dynamically controlled by surface melt rate and by the hydraulic potential in the channel draining the lake (Fig. 5). Our model outputs show that only two lakes retain a significant depth of water at the end of the melt season (L1 & L2), while L3 & L4 drain nearly 120 completely once melt ceases.

The three small, lake-free catchments (M5, M6, M7; Area $\leq 8 \text{ km}^2$) tend to have a larger relative diurnal amplitude and a shorter lag time than the large catchments with lakes (M1, M2, M3, M4; Area $\geq 19 \text{ km}^2$). From June to August 2012, for example, the diurnal amplitude for catchments M5–M7 is between 50–80% and only 20–50% for catchments M1–M4. For the same period, the lag time for M5–M7 is consistently 1–3 hours less than for M1–M4 (Fig. 3b, 4b). The separation is less clear 125 for August–September 2015, where recurring periods with no surface melt seem to obscure the trend (Fig. 3c, 4c).

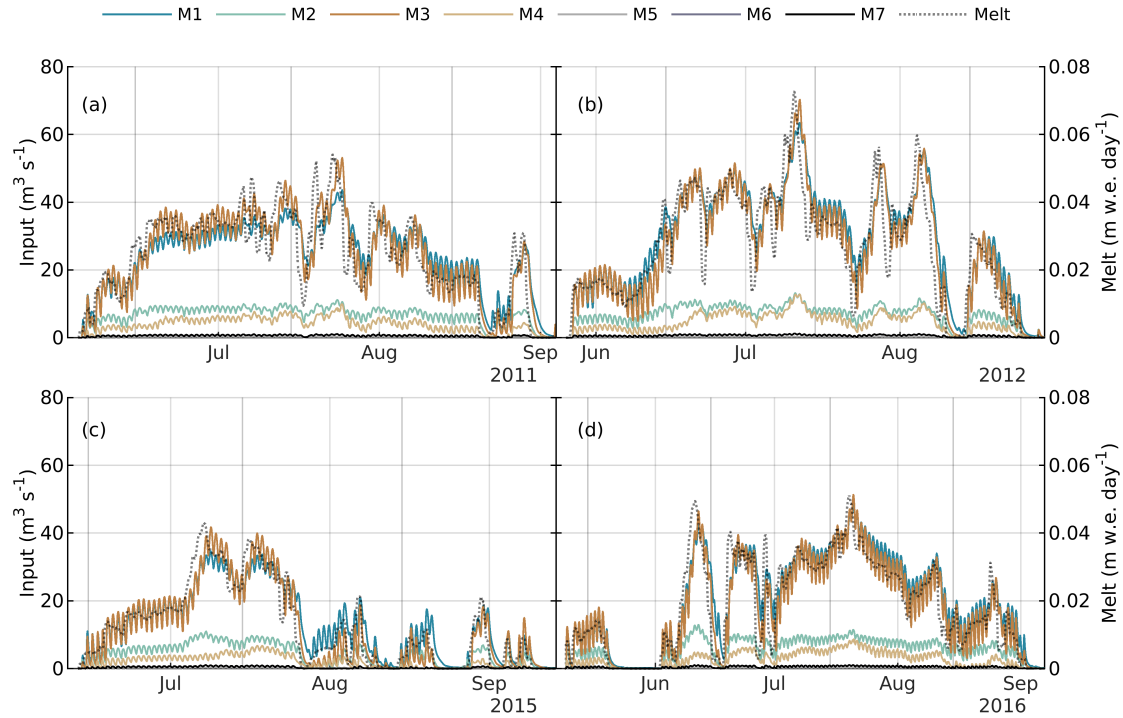

Figure 2. Surface inputs to moulins M1–M7 and domain-averaged 24-hour rolling mean RACMO2.3p2 surface melt rate (right axis, dotted grey curve) for (a) 2011, (b) 2012, (c) 2015, and (d) 2016.

Figures 2, 3, 4, and 5 suggest that surface melt is an important explanatory variable for the rate and diurnal amplitude of surface inputs to moulins, lag time between solar noon and peak moulin input, and lake water level. The extent to which surface melt rate controls these features can be quantified by comparing the squared correlation coefficient, R^2 , between melt rate and each of the moulin input rate, diurnal amplitude, lag time, and lake water level (R^2 is also equal to the proportion of variance explained by melt rate), and the p -value for the null hypothesis that the quantities are not related (Table 2). Quantities with a significant p -value ($p \lesssim 0.05$) can be interpreted as primarily driven by surface melt, while quantities with a low R^2 and/or $p > 0.05$ are instead dominated by internal or other external variability in the system, including seasonal changes in the extent of supraglacial channels (Fig. C1). The R^2 and p -values are computed for direct model outputs at 2-hour resolution and for daily means. Table S1 provides complete statistics for all quantities, sub-catchments, and years. For the remainder of the text, significant p -values below 0.01 are represented as $p < 0.01$. In Table 2 and S1, significant p -values below 10^{-16} are represented as 0.

Three of the five relationships considered in Table 2 are consistently significant across sub-catchments. Surface melt exerts the strongest control on the rate of inputs to moulins, with between 24% and 90% of the variance in daily mean moulin input explained by variations in diurnal-averaged melt rate ($p < 0.01$). The strength of the relationship varies year-to-year. In 2012,

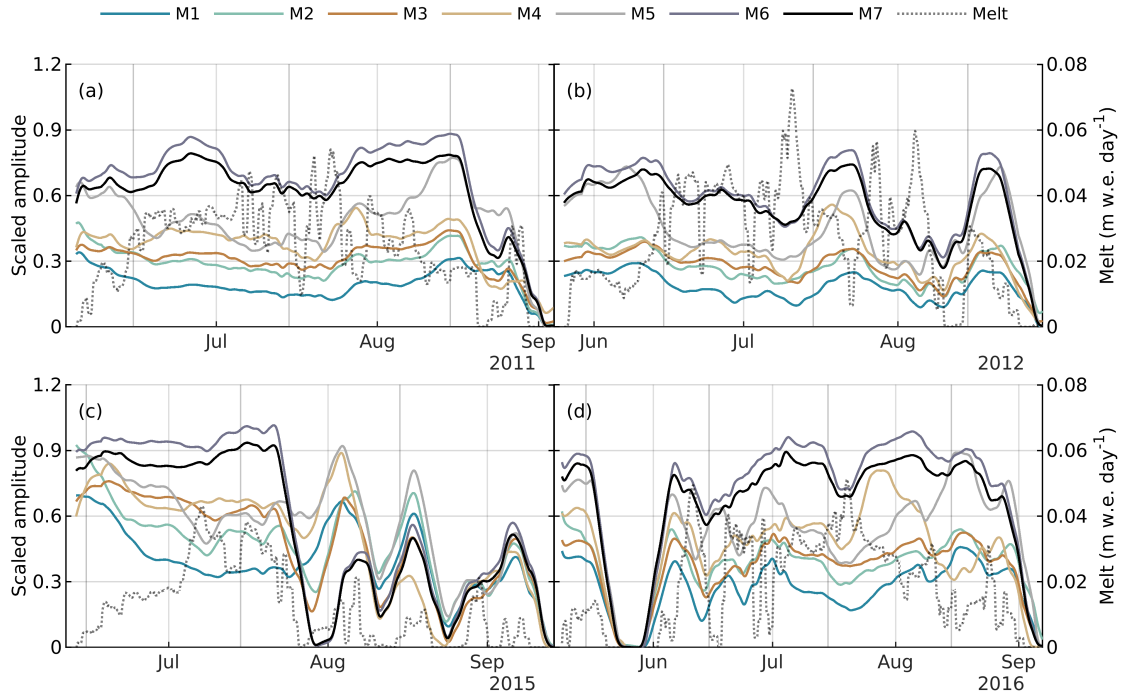

Figure 3. Relative diurnal amplitude of surface inputs to moulines (scaled by mean moulin input) and domain-averaged 24-hour rolling mean RACMO2.3p2 surface melt rate (right axis, dotted grey curve) for (a) 2011, (b) 2012, (c) 2015, and (d) 2016.

140 70–90% of variance is explained by melt rate ($p < 0.01$), while the maximum aside from 2012 is only 38% for M1 and M2
 in 2011 ($p < 0.01$). When we analyze 2-hour model outputs rather than the diurnal averages, the relationship is significant, but
 the proportion of variance in moulin input rate explained by surface melt rate is lower for all catchments and all years (9–31%;
 $p < 10^{-23}$; Table S1).

The relationships between surface melt and relative amplitude, and surface melt and lag time, are not robust across all years
 145 and sub-catchments. Outside of specific examples (e.g., 2015 for relative amplitude and 2012 for lag), variance in the amplitude
 and lag of moulin inputs is not significantly related to surface melt rate.

The water level in the four labelled supraglacial lakes is significantly controlled by melt rate, however this again varies
 between years. In 2012, 52–74% of variance in diurnal-averaged lake level for all four lakes is explained by diurnal-averaged
 melt rate ($p < 0.01$). In other years, $\leq 49\%$ of variance is explained by melt rate ($p < 0.01$), and in 2015 it is not clear the
 150 relationship is significant for L2 ($p = 0.06$). Melt rate exerts a weaker, yet still significant, control on lake level at the 2-hour
 timescale ($R^2 \leq 16\%$ for significant relationships with $p < 0.01$).

The relationship between lake level and the rate of input to the downstream moulin is significant in all years and all sub-
 catchments, at both daily and sub-daily timescales. Between 19–85% of variance in moulin input is explained by lake level at

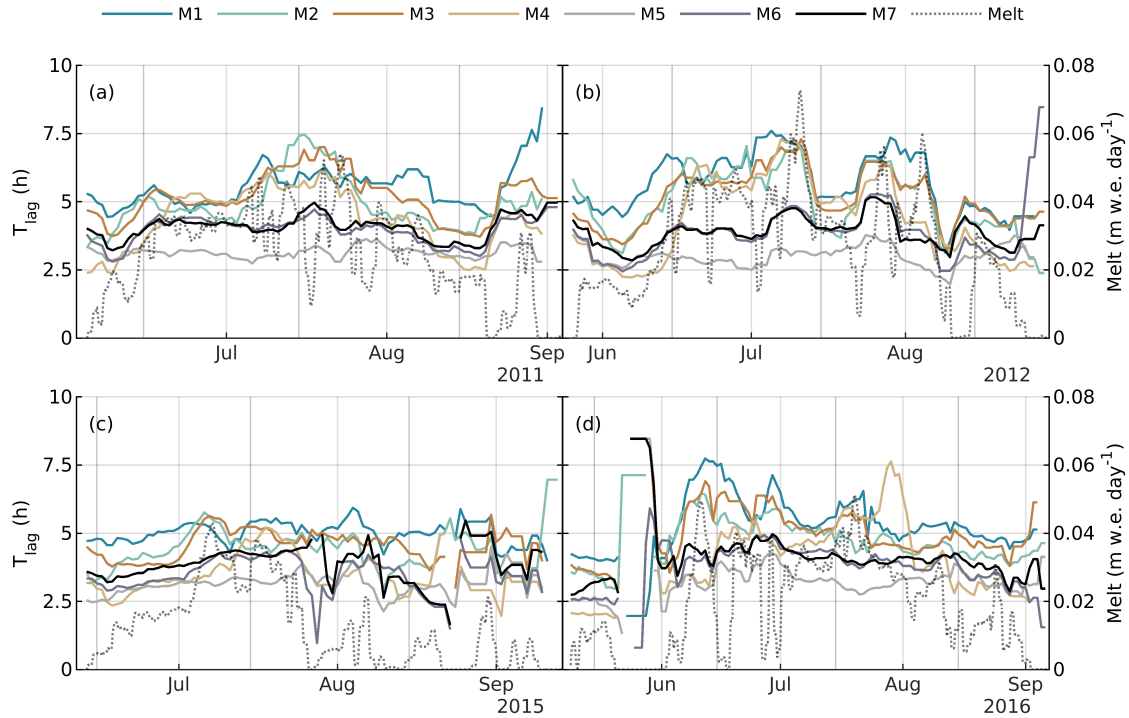

Figure 4. Seven-day moving-average time lag between local solar noon ($\sim 15:22$) and peak moulin input, and domain-averaged 24-hour rolling mean RACMO2.3p2 surface melt rate (right axis, dotted grey curve), for (a) 2011, (b) 2012, (c) 2015, and (d) 2016.

the sub-daily timescale, and 22–92% of variance in diurnal-averaged moulin input is explained by diurnal-averaged lake level
 155 with $p < 0.01$.

4 Discussion

4.1 Interannual variability in supraglacial drainage

The supraglacial drainage model predicts variations in the diurnal amplitude and time lag of moulin inputs in response to interannual variation in melt forcing intensity and duration (Fig. 3, 4). Different realizations of surface melt forcing, with
 160 different rates and durations of surface melt, result in differences in the relationship (e.g., R^2 and p -values) between surface melt and these quantities of interest. The significant relationships (moulin input–melt rate, lake level–melt rate, and lake level–moulin input) are strongest in the intense melt year 2012 and weakest in the lowest melt year (2015) (Table S1). For example, 78–90% of variance in diurnal-averaged moulin input is related to surface melt forcing, where the proportion is $< 38\%$ in all other years.

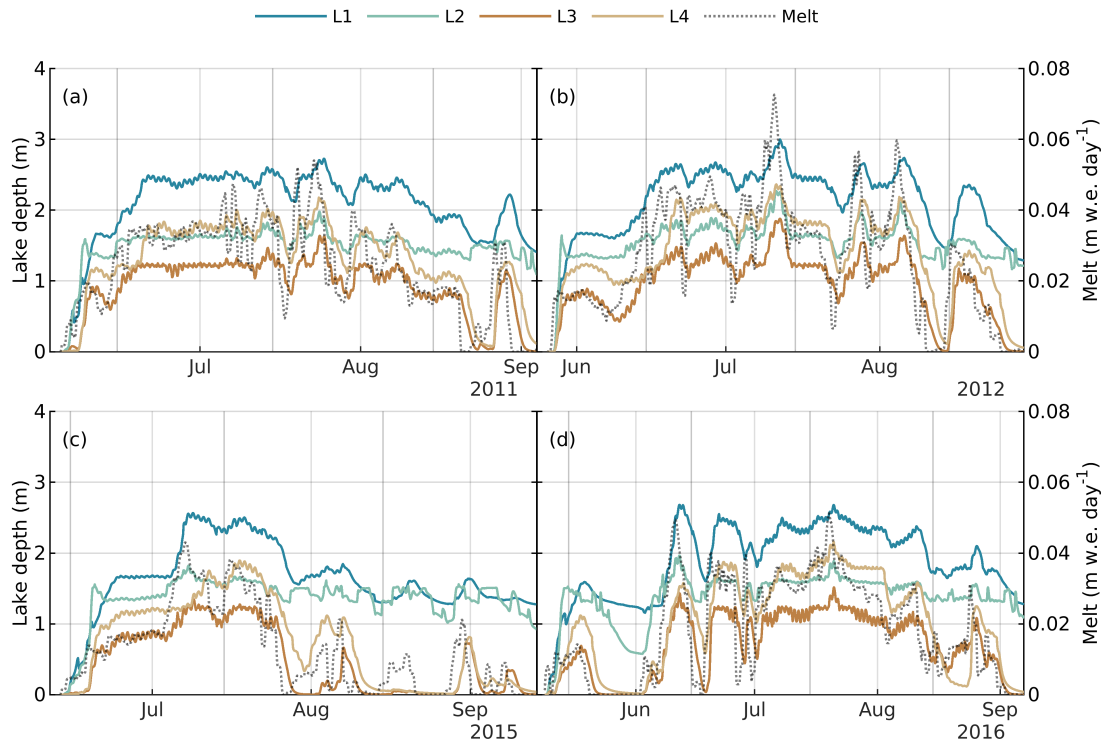

Figure 5. Supraglacial lake water depths and domain-averaged 24-hour rolling mean RACMO2.3p2 surface melt rate (right axis, dotted grey curve) for (a) 2011, (b) 2012, (c) 2015, and (d) 2016.

165 These relationships suggest that intense surface melt rates in 2012 (domain-averaged melt of $3.03 \text{ m w.e. a}^{-1}$ compared to $2.81 \text{ m w.e. a}^{-1}$ in 2016, the second most intense melt year) overwhelm internal variability (e.g., changes in supraglacial flow routing as lakes fill and drain, and as the channel network expands or contracts) and other external sources of variability. Internal variability instead becomes relatively more important in years with moderate melt forcing (2011, 2015, 2016). The discrepancy between the daily and sub-daily correlations (Table 2) suggests that internal variability is most important on timescales shorter than one day.

170

4.2 Seasonal trends in supraglacial drainage

Continuous seasonal trends in the amplitude and time lag of moulin inputs, as suggested by synthetic modelling (Yang et al., 2018; Hill and Dow, 2021), are not clear except in a few atypical cases. For example, in the year with the lowest surface melt (2015), the diurnal amplitude of inputs to moulins M1–M5 steadily decreases with a statistically significant trend ($p < 0.01$)

175 from the onset of surface melting on 13 June until a sharp increase in melt rates on 2 July despite relatively steady surface melt rates, perhaps as a result of a reduction in the extent of small supraglacial channels (Fig. C1). Over the same period, lag time is

Table 2. Squared correlation coefficients (R^2) and p -values for the null hypothesis that there is no relationship between the specified variables. Correlations and p -values are computed for each of the seven sub-catchments. The minimum and maximum R^2 values are the minimum and maximum values across the seven catchments, and the p values are the maximum value for the seven catchments. Correlation coefficients and p -values are computed for model outputs at native 2-hour resolution and binned into 24-hour increments. p -values $< 10^{-16}$ are represented by $p = 0$.

steady or slightly increasing aside from some transient behaviour in the first week of melting between 13 June and ~19 June (Fig. 3c, 4c).

Aside from limited examples of smooth, continuous seasonal trends, we observe discontinuous shifts in amplitude and time lag coinciding with rapid changes in surface melt rates. For example, in 2015 the relative diurnal amplitude of inputs to all seven moulins is tied to irregular melt intensities from ~27 July until the end of the melt season, ~12 September (Fig. 3c). The lack of continuous trends suggests that variations in surface melt rate are the primary control on moulin inputs compared to seasonal expansion and contraction of the supraglacial channel network (Fig. C1). The few examples of continuous trends (e.g., 13 June to 2 July 2015) occur during periods of steady surface melt rates, when the impact of the secondary controls (e.g., supraglacial channel evolution) are not obscured by melt rate variability.

4.3 Impact of supraglacial lakes

When they are present, supraglacial lakes influence the character of inputs to moulins. Large sub-catchments with lakes (M1–M4) have predominantly lower relative diurnal amplitude and longer lag times than the small catchments without lakes (M5–M7) (Fig. 4). The relationship between lake level and moulin inputs is evidenced by their correlation on diurnal ($0.22 \leq R^2 \leq$
190 0.92 ; $p < 0.01$) and sub-diurnal ($0.19 \leq R^2 \leq 0.89$; $p < 0.01$) timescales (Table 2). At least some of the remainder of the variance in moulin inputs is likely attributable to the fact that not all of the inputs to a moulin flow through the upstream lake, so that a proportion of the moulin inputs are unaffected by lake water level. The relationship between lake level and downstream moulin input is consistently stronger for lakes L3 and L4 (79–86%, $p < 0.01$ at daily scale), which do not have significant long-term storage, than for lakes L1 and L2 (19–77%; $p < 0.01$ at daily scale), which do store large volumes of
195 water.

Compared to Lakes L1 and L2, there is negligible water depth stored in L3 at the end of each melt season (5), and despite similar input rates through M3 as M1 (Fig. 2), moulin M3 has consistently higher relative diurnal amplitude and a shorter lag time than M1 (Fig. 5, Fig. 4). Since lake L3 is also the only lake to fully drain following a pause in surface melt from 26–28 July 2015 (Fig. 5c), Lake L3 appears to behave more like a floodplain along the main channel through its sub-catchment than
200 a lake with storage. This proposition is supported by the elongated shape of L3, lying directly along a main drainage channel, in the 8 July 2021 Landsat 8 scene (Fig. 1a).

Given the position of M4 directly within the L4 basin (this position explains the lack of long-term storage in L4), it's possible that L4 rapidly drains directly through M4, in contrast to the other lakes in the domain which could drain through unstable incision of their outlet channel (Kingslake et al., 2015). Satellite imagery from 8 July 2021 does not show a lake in the location
205 of L4, despite visible lakes upstream from our study site at higher elevations (Fig. 1a). Unfortunately, the dataset used to derive moulin locations (Yang and Smith, 2016) does not discriminate between stable and rapidly draining lakes, so we do not know if this is the case.

Aside from the combined influence of domain size and supraglacial lakes in modulating the amplitude and time lag of moulin inputs, there is no significant difference in the strength or significance of the relationship between surface melt and
210 moulin inputs, the amplitude of moulin inputs, or their timing between catchments with and without lakes (Table 2, S1). An unfortunate limitation of our model domain is that we can not completely disentangle the effects of catchment size and supraglacial lakes, since the four labelled lakes occupy the four largest catchments, so it's not possible to determine exactly the contrasting drivers of moulin input dynamics in catchments with and without lakes.

4.4 Streamflow observations

215 It remains difficult to constrain supraglacial drainage models such as SaDS due to a limited number of sufficiently long in-situ discharge records. We require a long (ideally entire melt-season) record since one of the primary advantages of SaDS is that it dynamically represents seasonal changes in the supraglacial drainage system efficiency. Muthyala et al. (2022) present one of the only sufficiently long continuous records (62 days from 2016) from a small (0.6 km^2) lake-free catchment in southwest

Greenland. Within our study site, catchments M6 & M7 are the most similar to the catchment instrumented by Muthyala et al. (2022). A detailed quantitative comparison by applying SaDS to the same catchment is not presently possible without complete in-situ data, since it would not be possible to separate discrepancy arising from differences in surface melt forcing and DEM surface elevations from discrepancy arising from model error. Despite this limitation, we can compare moulin inputs qualitatively.

For M6 & M7 (combined catchment area of 8.5 km²), we have modelled lag times between 2–5 hours, compared to 1–3 hours from Muthyala et al. (2022). SaDS predicts a relative diurnal amplitude of 50–100%, i.e., flow nearly pauses overnight, in qualitative agreement with data collected by Muthyala et al. (2022) showing stream discharge minimums near zero except during periods of elevated positive overnight energy balance. Muthyala et al. (2022) report similar abrupt shifts in the timing and amplitude of streamflow related to rapid changes in melt forcing as are observed from the SaDS outputs (Fig. 2, 3, 4). Muthyala et al. (2022) also report a statistically significant decrease in the lag time between solar noon and peak streamflow from 25 June until 4 August 2016, terminating when daily minimum air temperatures decreased from $\sim 3^{\circ}\text{C}$ to $\sim 1^{\circ}\text{C}$. We do not capture similar trends in lag time in our model outputs, however we have identified periods of continuous trends in the diurnal amplitude of moulin inputs that terminate with a rapid shift in surface melt rates. Since we have observed that melt rate variations mask seasonal trends, it remains possible that we would observe such a trend in lag time with a different melt forcing timeseries. Despite these specific details, the streamflow measurements (Muthyala et al., 2022) demonstrate a similar pattern of a melt rate-dominated system, with internal dynamics (e.g., changes in the extent of supraglacial streams, filling and drainage of supraglacial lakes) as a secondary control that becomes important during periods of steady surface melt rates.

It is also possible to compare our model results to shorter measurement campaigns, however these comparisons do not constrain the seasonal evolution of supraglacial behaviour. For the $\sim 60\text{ km}^2$ Rio Behar catchment (67.047°N , -49.033°W) with flow $<40\text{ m}^3\text{ s}^{-1}$ in the main river stem leading to the terminal moulin, Smith et al. (2017) report a lag time of 5.5 hours from Acoustic Doppler Current Profiler (ADCP) measurements from 20 to 23 July 2015, and Smith et al. (2021) report a lag time of 6 hours from repeated ADCP measurements on the same river segment from 6 to 13 July 2016. Our modelled inputs for moulins M1 and M3 ($\lesssim 40\text{ m}^3\text{ s}^{-1}$ in 2011, 2015, and 2016) have similar input rates to the Rio Behar measurements and show a similar lag time ($\sim 4\text{--}7$ hours). Lag times for M1 and M3 are higher in 2012 ($\sim 5\text{--}7$ hours) when the absolute magnitude of moulin inputs is also much larger (up to $>60\text{ m}^3\text{ s}^{-1}$).

These comparisons suggest that SaDS predicts reasonable lag times and amplitudes compared to observations with similar discharges. However, given the currently available observational data, it remains difficult to calibrate the model and determine the most relevant mechanisms by which supraglacial drainage evolves. A full calibration dataset would ideally contain streamflow observations spanning multiple orders of discharge magnitude, measurements of lake water level, and the evolution of channel cross sections, for a significant portion of the melt season.

250 4.5 Model intercomparison and selection

SaDS is among the models with the most complete supraglacial hydrologic process representation, including both channelized and distributed drainage, filling and draining of supraglacial lakes, and dynamically computed seasonal evolution of

supraglacial stream density. Compared to flow-routing type models (e.g. Banwell et al., 2012; Yang et al., 2018), travel times in SaDS depend on upstream flow accumulation and melt rate, so that the time lag and relative diurnal amplitude of moulin inputs varies in a complex way with melt forcing.

Modelled water levels in supraglacial lakes fluctuate by several centimeters in response to diurnal melt variations and by up to a meter over a few days in response to larger changes in melt intensity. It is not clear how this variation is partitioned between nonlocal processes such as downstream channel capacity adjustment and local processes such as excess meltwater transiently being stored in lakes. These rapid fluctuations in lake level may partly explain the residual variance in the timing of rapid lake drainage not explained by strain rates (Poinar and Andrews, 2021). However, these fluctuations may not be captured by models treating lakes as holding a prescribed storage volume (e.g. Banwell et al., 2012).

An incised channel network (c.f. Leeson et al., 2012) is important for efficiently routing large volumes of meltwater into moulins (Yang et al., 2018; Gleason et al., 2021). Channel density may also change through the melt season, changing the response of moulin inputs to melt forcing (Yang et al., 2022). Compared to these models, SaDS dynamically evolves channel density based on the local balance between incision and melt-out.

The process-based approach taken by SaDS increases the computational cost well over that of other models (~ 7 days per year of simulation time in the configuration presented here). This tradeoff between physics and computational cost yields a spectrum of models from which the appropriate model must be chosen for each application so as not to neglect key features of supraglacial drainage.

We recommend choosing the appropriate supraglacial drainage model based on the sensitivity of a prospective modelling study to the supraglacial drainage characteristics that we have highlighted here. If short-term (< 1 day) variations in the rate, amplitude, and time lag of moulin inputs will materially change the results of the modelling study, for example when modelling the short-timescale variations in moulin water storage (e.g. Andrews et al., 2022), it may be important to use a detailed process-resolving model such as SaDS. If only aggregate quantities, e.g. the total volume of moulin inputs on seasonal timescales for assessing centennial-scale changes in ice sheet subglacial hydrology, are relevant, it should be possible to carefully select a less expensive model that captures moulin inputs with an appropriate level of detail (e.g., Banwell et al., 2012; Leeson et al., 2012; Yang et al., 2018). The more difficult case is where day-to-day variation in the character of moulin inputs will impact the modelling study results in a noticeable way, and where the computational cost of a process-resolving supraglacial hydrology model will be a rate-limiting step in the modelling workflow. For example, this may be the case when modelling subglacial drainage on seasonal timescales. Here, the sensitivity of the outcomes of the modelling study (e.g., diurnal and seasonal variations in subglacial effective pressure) to the character of moulin inputs could be quantified by carrying out benchmark simulations with simpler models (e.g., Yang et al., 2018) with varying parameters. The experimenter can then make an informed decision on the appropriate supraglacial drainage model based on the known sensitivity. For example, it would be valuable to combine process-resolving supraglacial (e.g., SaDS), englacial (Andrews et al., 2022), and subglacial (e.g., GlaDS; Werder et al., 2013) models to quantify the sensitivity of subglacial drainage to supraglacial and englacial processes.

5 Conclusions

We have presented model outputs of supraglacial meltwater flow, lake filling and draining, and surface inputs to moulins for a small ($\sim 20 \times 27 \text{ km}^2$) catchment on the Greenland Ice Sheet for four years, including the extreme melt year in 2012. The relationship between surface melt and the magnitude, relative diurnal amplitude, and timing of surface inputs to moulins is
290 complex and sensitively depends on the duration and intensity of surface melt. In years with intense surface melt (e.g., 2012), surface melt is the primary driver of variations in moulin inputs ($R^2 > 0.78$; $p < 0.01$). In years with more moderate melt rates, melt rate is a weaker control ($R^2 < 0.38$; $p < 0.01$), since internal variability (e.g., the physics captured by the SaDS model) becomes more important.

Supraglacial lakes exert a strong control on moulin inputs. The four large catchments with supraglacial lakes within our
295 domain have consistently lower diurnal amplitude in moulin inputs and a longer time lag between solar noon and peak moulin input than the three small catchments without lakes. However, since we find lakes only in the largest catchments, the relative contributions of catchment scale and lakes can not be fully disentangled with the current model outputs.

SaDS model outputs contain similar key features (time lag and diurnal amplitude) to in-situ streamflow observations from a nearby catchment (Muthyala et al., 2022). However, given the two orders of magnitude spanned by moulin inputs within our
300 study site, we can not yet observationally constrain SaDS without additional long-term stream discharge records spanning a wide range of discharge magnitudes and for catchments with and without lakes.

By placing these results in the context of existing drainage models with differing levels of process representation and computational expense, we have suggested a conceptual model for selecting the appropriate drainage model for a prospective modelling study. The supraglacial model should be chosen based on expected or demonstrated sensitivity to the exact nature
305 of moulin inputs. A process-resolving model such as SaDS is expected to be advantageous when variations in the amplitude and timing of moulin inputs on sub-daily timescales will substantially change the outcomes of the prospective modelling study. When only a broad representation of moulin inputs is required, simpler routing models are expected to be appropriate and come with a substantially reduced computational cost.

Appendix A: Model description

310 SaDS follows the general structure of the GlaDS model (Werder et al., 2013). The model is posed on an unstructured triangular mesh with distributed sheet-like flow across elements and discrete channelized flow along edges. The key dynamic equations are reviewed here; for full details refer to Hill and Dow (2021).

A1 Distributed drainage

Distributed flow across the ice surface is governed by conservation of mass, written in terms of the flow depth h_s ,

$$315 \quad \frac{\partial h_s}{\partial t} + \nabla \cdot \mathbf{q}_s = m_s + \frac{\Xi_s}{\rho_w L} - \frac{m_e}{l}, \quad (\text{A1})$$

for discharge per unit width \mathbf{q}_s , distributed melt rate m_s , and potential energy dissipation Ξ_s . The final term represents the rate of mass transfer m_e into a channel with length l . Constants are density of water ρ_w and latent heat of fusion L . The discharge \mathbf{q}_s is approximated with a Darcy-Weisbach-like equation,

$$\mathbf{q}_s = -k_s h_s^{\alpha_s} \left| \frac{\nabla \phi_s}{\rho_w g} \right|^{\beta_s - 2} \frac{\nabla \phi_s}{\rho_w g}, \quad (\text{A2})$$

320 for hydrostatic potential ϕ_s , conductivity k_s , and gravity g . Exponents α_s and β_s control the form of the equivalent Darcy friction factor.

A2 Channelized drainage

Supraglacial channels are parameterized by the total incision depth of the channel H_c and the depth of water flowing in the channel h_c . The channel width is assumed to be related to channel depth by $w_c = r H_c$ for a constant and uniform width-to-
325 depth ratio r . The dynamic evolution of channel incision depth is governed by the balance between melt along the channel bed and walls by potential energy dissipation and melt-out of the adjacent ice surface,

$$\frac{dH_c}{dt} = \frac{1}{2} \frac{\rho_w}{\rho_i} (m_c - m_s) + \frac{1}{2w_c} \frac{\Xi_c}{\rho_i L}, \quad (\text{A3})$$

for channel bed melt rate m_c , sheet melt rate m_s , potential energy dissipation Ξ_c , and ice density ρ_i .

The dynamic evolution of channel flow depth is given by conservation of mass,

$$330 \quad w_c \frac{\partial h_c}{\partial t} + \frac{\partial q_c}{\partial t} = w_c m_c + \frac{\Xi_c}{\rho_w L} - h_c \frac{\partial w_c}{\partial t} + m_e, \quad (\text{A4})$$

where the channel discharge q_c is computed with an analogous expression to (A2) using the channel hydrostatic potential, $\phi_c = \rho_w g z_c + \rho_w g (h_c - H_c)$, for channel lip elevation z_c . m_e represents mass transfer from the distributed system into the channel.

A3 Drainage system coupling

335 Unlike GlaDS, SaDS uses different hydraulic potentials in distributed (ϕ_s) and channelized (ϕ_c) systems, so SaDS requires an explicit rule to exchange mass between the systems. The mass exchange over an edge of length l is computed as

$$m_e = f l q_n, \quad (\text{A5})$$

for exchange fraction f and normal flux $q_n = \mathbf{q}_s \cdot \mathbf{n}$ where \mathbf{n} is the outward unit normal of the edge. The exchange fraction f depends on the difference in potential between the channel and adjacent sheets such that mass is only transferred into the
340 channel when the channel potential is less than the sheet potential.

Table A1. SaDS model parameters.

Parameter	Description	Value	Units
α_s	Distributed sheet flow exponent	$\frac{5}{4}$	-
β_s	Distributed sheet flow exponent	$\frac{3}{2}$	-
α_c	Channel flow exponent	$\frac{5}{3}$	-
β_c	Channel flow exponent	$\frac{3}{2}$	-
k_s	Distributed sheet hydraulic conductivity	1.0	$\text{m}^{(2-\alpha_s)} \text{s}^{-1}$
k_c	Channel hydraulic conductivity	15	$\text{m}^{(2-\alpha_c)} \text{s}^{-1}$
r	Channel width-to-depth ratio	5.0	-
ζ	Exchange ratio	0.2	-
dt	Timestep	20	s
ρ_i	Density of ice	910	kg m^{-3}

Appendix B: Temporal interpolation of RACMO melt rate

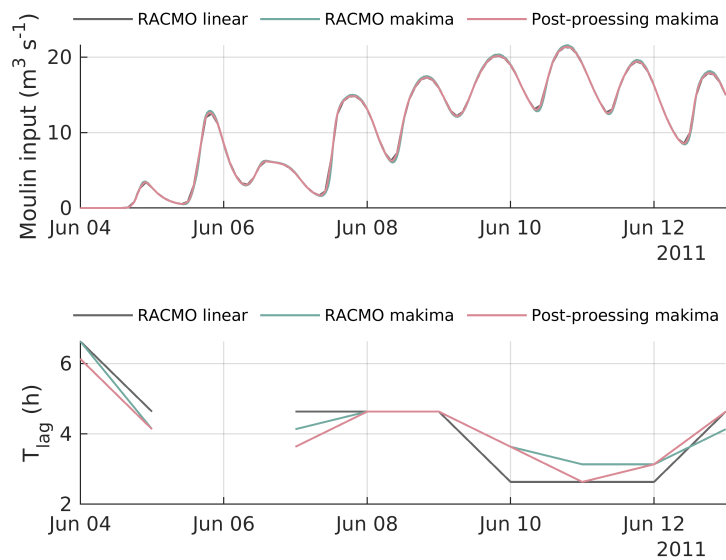

Figure B1. Comparison of the rate of surface inputs to moulins (a) and the time lag between local solar noon and peak moulin inputs (b) for the beginning of the 2011 melt season for three interpolation schemes. (1) ‘RACMO linear’ uses linear interpolation to downscale RACMO from native 3 hour resolution to the 20 s model timestep and no post-processing interpolation to compute time lag. (2) ‘RACMO makima’ uses modified Akima interpolation to downscale RACMO from 3 hour to 20 s timestep and no post-processing interpolation to compute time lag. (3) ‘Post-processing makima’ uses linear interpolation to run the model, and interpolates model outputs onto 30 min timesteps using modified Akima interpolation before computing lag time.

Appendix C: Seasonal changes in the channel network

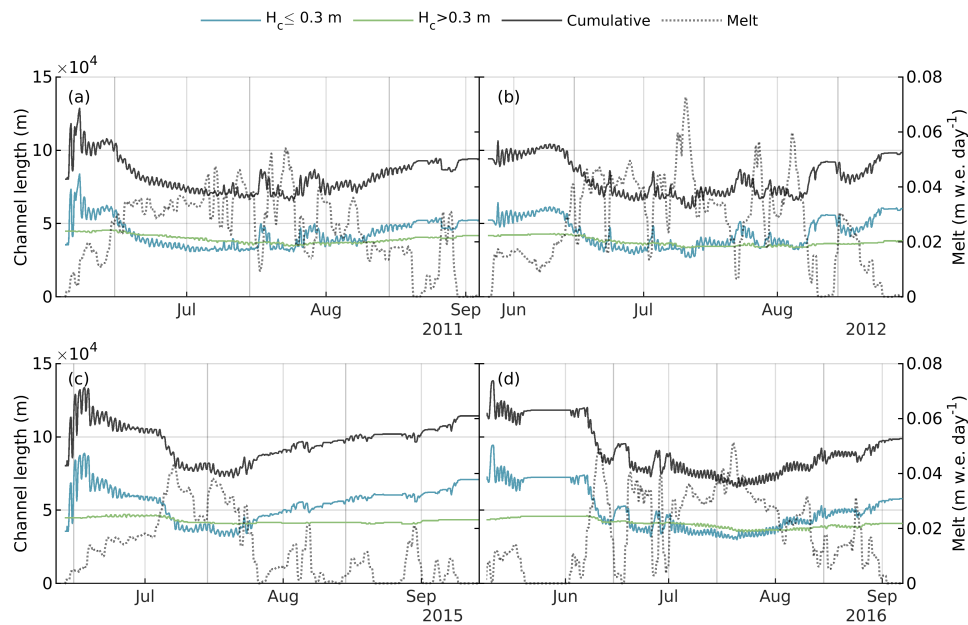

Figure C1. Total length of incised supraglacial channel network, partitioned between small (incision depth less than or equal to 0.3 m) and large (incision depth greater than 0.3 m) channels, for (a) 2011, (b) 2012, (c) 2015, (d) 2016, and domain-averaged 24-hour rolling mean RACMO2.3p2 surface melt rate (right axis, dotted grey curve).

Code and data availability. ArcticDEM data are freely available from the Polar Geospatial Center (<https://www.pgc.umn.edu/data/arcticdem/>). RACMO surface melt data are available by contacting the Institute for Marine and Atmospheric research Utrecht University (<https://www.projects.science.uu.nl/iceclimate/models/racmo.php>). The SaDS model is described fully in Hill and Dow (2021) including equations and implementation. Table S1 and all model outputs and code to produce the figures are available at <https://doi.org/10.5281/zenodo.7776530>.

Author contributions. T Hill contributed to conceptualization, analysis, methodology, software, visualization, writing and reviewing. C Dow contributed to conceptualization, analysis, methodology, supervision, and reviewing & editing.

Competing interests. The authors declare that they have no conflict of interest.
