20 **Key points**

- 21
- 22 • We estimate mean accumulation rates for the past ~4700 years across the Pine Island,
23 Thwaites, and Institute and Möller ice-stream catchments in West Antarctica using a
24 ubiquitous, ice-core dated internal radar reflection
 - 25 • Accumulation rates were 18% higher during the mid-Holocene compared to modern rates
26 over the Amundsen-Weddell-Ross divide
 - 27 • Spin-up of regional and continental ice-sheet models should include time-varying changes in
28 Holocene accumulation rates from the WAIS Divide Ice Core to generate more realistic
29 grounding-line evolution and past sea level rise contribution across this region

30 **Abstract**

31

32 Understanding the past and future evolution of the Antarctic Ice Sheet is challenged by the availability
33 and quality of observed palaeo-boundary conditions. Numerical ice-sheet models often rely on these
34 palaeo-boundary conditions to guide and evaluate their models' predictions of sea-level rise, with
35 varying levels of confidence due to the sparsity of existing data across the ice sheet. A key data source
36 for large-scale reconstruction of past ice-sheet processes are Internal Reflecting Horizons (IRHs)
37 detected by Radio-Echo Sounding (RES). When IRHs are isochronal and dated at ice cores, they can
38 be used to determine palaeo-accumulation rates and patterns on large spatial scales. Using a spatially
39 extensive IRH over Pine Island Glacier, Thwaites Glacier, and Institute and Möller Ice Streams
40 (covering a total of 610 000 km² or 30% of the WAIS), and a local layer approximation model, we infer
41 mid-Holocene accumulation rates over the slow-flowing parts of these catchments for the past ~4700
42 years. By comparing our results with modern climate reanalysis models (1979 – 2019) and
43 observational syntheses (1651 – 2010), we estimate that accumulation rates over the Amundsen-
44 Weddell-Ross divide were on average 18% higher during the mid-Holocene than modern rates.
45 However, no significant spatial changes in the accumulation pattern were observed. The higher mid-
46 Holocene accumulation-rate estimates match previous palaeo-accumulation estimates from ice-core
47 records and targeted RES surveys over the ice divide, and they also coincide with periods of grounding-
48 line readvance during the Holocene over the Weddell and Ross Sea sectors. We find that our spatially-
49 extensive, mid-Holocene-to-present accumulation estimates are consistent with a sustained late-
50 Holocene period of higher accumulation rates occurring over millennia reconstructed from the WAIS
51 Divide Ice Core, thus indicating that this ice core is spatially representative of the wider West Antarctic
52 region. We conclude that future regional and continental ice-sheet modelling studies should base their
53 climatic forcings on time-varying accumulation rates from the WAIS Divide Ice Core through the
54 Holocene to generate more realistic predictions of the West Antarctic Ice Sheet's past contribution to
55 sea-level rise.

60

61 1. Introduction

62 Improving our knowledge of past climatic changes over the Antarctic Ice Sheet is required if we
63 are to understand its present evolution and model its future under increasingly rapid climatic changes
64 (IPCC, 2021). Most studies of past ice-sheet behaviour over Antarctica have focused on modelling
65 changes in ice volume and grounding-line retreat following the Last Glacial Maximum (LGM, ~20 ka
66 Before Present, BP) (Denton and Hughes, 2002; Golledge et al., 2012; 2013; Hillenbrand et al., 2013;
67 2014; Le Brocq et al., 2011; Kingslake et al., 2018); however, less attention has been paid to ice-sheet
68 evolution during the Holocene (~11.7 ka BP to present). Recent evidence suggests that parts of the
69 grounding line of West Antarctica may have retreated several hundred kilometres inland from its
70 current position at ~10 ka and subsequently readvanced to reach its modern position sometime during
71 the Holocene, due to isostatic rebound and climate-induced changes, particularly over the Weddell
72 Sea and western Ross Sea sectors (Siegert et al., 2013; Bradley et al., 2015; Kingslake et al., 2018;
73 Wearing and Kingslake, 2019; Venturelli et al., 2020; Neuhaus et al., 2021; Johnson et al., 2022).
74 However, the atmospheric and ice-dynamical conditions farther inland, which could also have
75 induced grounding-line migration, remain poorly constrained. An early investigation by Whillans
76 (1976) using radar data near Byrd Ice Core indicated stability during the Late Pleistocene and
77 Holocene epochs. Records of temperature and precipitation from the WAIS Divide Ice Core (hereafter
78 abbreviated as WD14; Fig. 1) in the central West Antarctic Ice Sheet (WAIS) suggest higher
79 accumulation rates during the Holocene than at present (Fudge et al., 2016), a trend that is also
80 observed across small parts of the Amundsen-Weddell-Ross divide (Fig. 1) near the WAIS Divide Ice
81 Core (hereafter referred to as WD14; Fig. 1) where isolated Radio-Echo Sounding (RES) surveys
82 have shown 15-30% higher accumulation rates during the mid-Holocene compared to modern values
83 (Siegert and Payne, 2004; Neumann et al., 2008; Koutnik et al., 2016).

84 Many numerical ice-sheet models that aim to predict Antarctica's long-term (past and future)
85 contribution to sea-level rise use past ice-sheet reconstructions from after the LGM to guide and
86 evaluate their models (Chavaillaz et al., 2013; DeConto and Pollard, 2016; Bracegirdle et al., 2019).
87 However, even well-used ice-sheet reconstructions assume that the ice sheet retreated continuously
88 throughout the Holocene (e.g. RAISED Consortium, 2014), a finding that has been challenged
89 recently for the WAIS (e.g. Kingslake et al., 2018). Further, significant discrepancies between model
90 simulations and the palaeo-proxy record currently impede our ability to predict confidently how the
91 ice sheet will respond to future changes in the climate (e.g. Johnson et al., 2021). While improvements
92 in model parameterisations are needed to close this gap (Bracegirdle et al., 2019; Sutter et al., 2021),
93 considerable improvement in the availability and quality of palaeo-proxy records, particularly during
94 the Holocene, is also needed to provide better constraints for ice-sheet models and ultimately better
95 resolve past ice-sheet changes (Kingslake et al., 2018; Jones et al., 2022). Palaeo-proxy data have
96 traditionally come from point-based measurements, such as ice cores (e.g. Petit et al., 1999; Parrenin
97 et al., 2007; WAIS Divide Project Members, 2013; Buizert et al., 2021), sediment cores (e.g.
98 Hillenbrand et al., 2013; Arnd et al., 2017; Hillenbrand et al., 2017; Kingslake et al., 2018; Venturelli
99 et al., 2020; Neuhaus et al., 2021; Sproson et al., 2022), or surface-exposure dating (e.g. Stone et al.,
100 2003; Suganuma et al., 2014; Johnson et al., 2014; Hein et al., 2016; Nichols et al., 2019; Johnson et
101 al., 2020; Braddock et al., 2022). A complimentary and spatially extensive alternative data source for
102 inferring past climate across an ice sheet is provided by Internal Reflecting Horizons (IRHs) detected
103 by RES. They primarily result from englacial acidity contrasts and are often detected for hundreds of
104 kilometres on RES data (Harrison, 1973; Bingham and Siegert, 2007). When employed in
105 combination with ice-core stratigraphies, IRHs can be used to extend age-depth relationships away
106 from an ice core by following peaks in electromagnetic return power in the radar data (e.g. Beem et
107 al., 2021; Bodart et al., 2021a; Cavitte et al., 2016; Jacobel and Welch, 2005; MacGregor et al., 2015;
108 Whillans, 1976; Winter et al., 2019).

109 In contrast to East Antarctica and Greenland, IRH extension of WAIS ice cores has so far
110 been challenging due to fewer deep ice cores there and, until recently, the lack of well-dated IRH
111 datasets. However, efforts have intensified in recent years to improve our understanding of ice
112 stratigraphy over this sector. In particular, four recent studies using airborne RES data (Karlsson et al.,
113 2014; Muldoon et al., 2018; Ashmore et al., 2020a; Bodart et al., 2021a) all identified a distinct and
114 bright IRH dated using the Byrd and WD14 ice-core chronologies to 4.72 ± 0.28 ka BP (Muldoon et
115 al., 2018; Bodart et al., 2021a). A comparison of volcanic sulphate deposition within the WD14 and
116 Siple Dome ice cores revealed a large peak in sulphate concentration matching the age and depth of
117 this ubiquitous IRH (Kurbatov et al., 2006; Bodart et al., 2021a; Cole-Dai et al., 2021; Sigl et al.,
118 2022), which we hereafter term the “4.72 ka IRH”. This IRH has now been observed by multiple RES
119 systems and extends throughout much of the slower-flowing ice of the Amundsen and Weddell Sea
120 embayments ($< 400 \text{ m a}^{-1}$), including across the divides demarcating regions draining into the
121 Amundsen, Weddell and Ross Seas.

122 Despite their potential wide-ranging applications, the incorporation of IRHs into ice-sheet
123 models has so far been limited compared to other types of palaeo-proxy data, primarily because the
124 inference of accumulation-rate or ice-flow history from IRHs is an ill-posed inverse problem
125 (Waddington et al., 2007). Previous applications using IRHs to inform regional and continental
126 models include: (a) constraining decadal-scale Surface Mass Balance (SMB) estimates from
127 atmospheric models using annually-resolved IRHs found in the shallow firn (Medley et al., 2013;
128 2014; Van Wessem et al. 2018; Dattler et al., 2019; Kaush et al., 2020; Cavitte et al., 2022); (b)
129 inferring past accumulation rates going back further in time (i.e. 100s to 1000s years) with the aim of
130 comparing past accumulation estimates with modern times (e.g. Leysinger Vieli et al., 2004; Siegert
131 and Payne, 2004; Neumann et al., 2008; MacGregor et al., 2009; 2016; Leysinger Vieli et al., 2011;
132 Cavitte et al., 2018); or (c) integrating both their characteristics (e.g. elevation in the ice) and the
133 information inferred from them (e.g. accumulation or basal-melt rates) to evaluate the output from
134 regional and continental ice-sheet models (Leysinger Vieli et al., 2011; 2018; Holschuh et al., 2017;
135 Sutter et al., 2021). Promisingly, Sutter et al. (2021) recently showed that spatially extensive Antarctic
136 IRHs can provide unique benchmarks for constraining ice-sheet model parameterisations (i.e. climate
137 forcing and simulated ice flow), which are then used to simulate palaeo ice-sheet evolution. Together,
138 these studies indicate multiple avenues for ice-sheet models to assimilate IRHs to further improve
139 estimates of past, current and future ice-sheet changes.

140
141 Here, we estimate mid-Holocene accumulation rates across the WAIS from first-order
142 calculations using a one-dimensional (1-D) model, constrained by the spatially extensive 4.72 ka IRH.
143 We first describe the data, the model used and their limitations and uncertainties (Sect. 2). We then
144 present our accumulation-rate estimates and compare them to observed and modelled modern
145 accumulation rates to reveal a longer-term perspective on changes between the mid-Holocene and the
146 present (Sect. 3). Finally, we place our results in the context of previous studies that consider WAIS
147 evolution during the Holocene (Sect. 4).

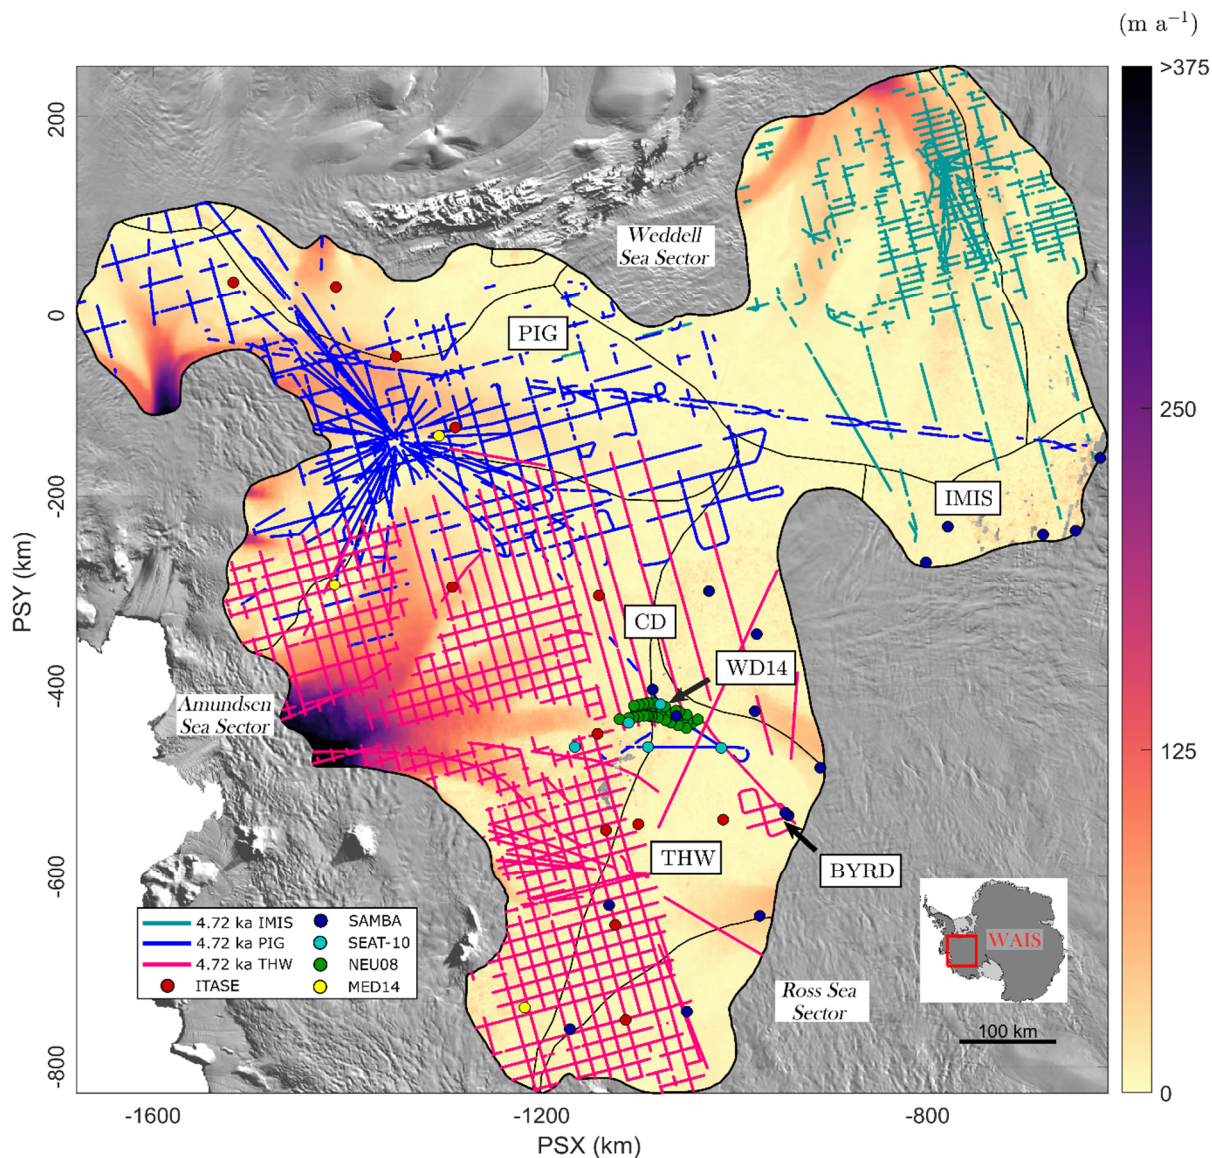

148 **2. Data and methods**

149

150 **2.1 Along-track IRH data**

151 We used data from extensive (~91 000 flight-track km) RES surveys acquired across West
152 Antarctica between 2004 and 2018. The main contributing surveys are the University of Texas
153 Institute for Geophysics (UTIG) 2004-2005 AGASEA survey flown over Thwaites Glacier (THW)
154 and Marie Byrd Land which deployed the 60-MHz High Capability Airborne Radar Sounder
155 (HiCARS) radar system (Holt et al., 2006; Peters et al., 2007), and the British Antarctic Survey (BAS)
156 2004-05 BBAS survey over Pine Island Glacier (PIG) and 2010-2011 IMAFI survey over Institute
157 and Möller Ice Streams (IMIS) which deployed the 150-MHz Polarimetric Airborne Survey
158 INstrument (PASIN) radar system (Vaughan et al., 2006; Corr et al., 2007; Ross et al., 2012; Frémand,

159 Bodart et al., 2022) (Fig. 1; Table 1). Additional profiles from NASA’s Operation Ice Bridge (OIB;
 160 MacGregor et al., 2021) 2016 and 2018 surveys, flown with the 195-MHz Multichannel Coherent
 161 Radar Depth Sounder 2 (MCoRDS-2) radar system (CRISIS, 2018), were also used to extract IRH
 162 information near the WD14 Ice Core and upper IMIS catchments (Bodart et al., 2021a; Figure 1 and
 163 Table 1). We refer the reader to the above references for comprehensive details on each system’s
 164 capabilities.

165
 166 Figure 1. Map of the datasets and key locations in this study. The three datasets that contain the 4.72 ka
 167 IRH are colour-coded as IMIS (green), PIG (blue), and THW (pink). IRH data where $D > 1$ are excluded (see
 168 Section 2.2.1; Figure S1). Points represent the snow, firn and ice cores used in this study to compare modern
 169 accumulation rates with those inferred from the 4.72 ka IRH (Sect. 2.4). The background colour map shows
 170 modern surface speeds from Rignot et al. (2017). Locations mentioned in this paper are abbreviated on the map,
 171 as follows: BYRD (Byrd Ice Core), IMIS (Institute and Möller Ice Streams), PIG (Pine Island Glacier), THW
 172 (Thwaites Glacier), WAIS (West Antarctic Ice Sheet), CD (Central Amundsen-Weddell-Ross Divide), WD14
 173 (WAIS Divide Ice Core). Major ice divides are from Mouginito et al. (2017). The background image is the 2014
 174 MODIS mosaik of Antarctica (Haran et al., 2018). For all analysis and figures in this study, the SCAR Antarctic
 175 Polar Stereographic projection is used (PSX/PSY; EPSG: 3031).

176 These RES surveys were used to track and date six IRHs spanning the Late Pleistocene and
 177 Holocene (25.7 – 2.3 ka BP) that collectively cover much of the WAIS, including IMIS (Ashmore et

178 al., 2020a), PIG (Karlsson et al., 2014; Bodart et al., 2021a) and THW (Muldoon et al., 2018). Here
 179 we only consider the 4.72 ka IRH mapped in all four studies and shown in Figure 1, as it is by far both
 180 the most spatially extensive and the only commonly traced IRH across all studies. We first merged all
 181 data points from the 4.72 ka IRH across the three catchments, resulting in a cumulative distance of
 182 ~40 000 line-km of IRH profiles (44% of the RES surveys' total coverage; Table 1). Although the
 183 along-track RES data were acquired with a trace spacing of between 10 and 35 m, depending on the
 184 dataset used, we re-sampled these points to 500 m in the along-track direction. We then added a
 185 spatially invariant firm correction of 10 m onto the Muldoon et al. (2018) dataset to match the same
 186 firm correction applied by the other studies to correct the IRH depth. Finally, we calculated the median
 187 value of all ice thicknesses and IRH depths falling within each 500 m interval.

188 Table 1. Characteristics of each IRH dataset used in this study that contain the 4.72 ka IRH. 'Reflector
 189 1' in Muldoon et al. (2018) is abbreviated here as 'R1'.

<i>Survey name</i>	<i>Survey provider</i>	<i>RES system</i>	<i>Dataset reference</i>	<i>Cumulative IRH distance (10³ km)</i>
IMAFI	BAS	PASIN 150-MHz	H2 in Ashmore et al. (2020a)	15
BBAS / OIB	BAS / NASA	PASIN 150-MHz / MCoRDS-2 195-MHz	R2 in Bodart et al. (2021a)	6
AGASEA	UTIG	HiCARS 60-MHz	R1 in Muldoon et al. (2018)	19

190 2.2 Inferring accumulation rates

191 To infer accumulation rates from the 4.72 ka IRH, we used the Nye model, a 1-D ice-flow
 192 model widely used for estimating accumulation rates and age-depth relationships over relatively slow-
 193 flowing parts of an ice sheet (Nye, 1957; Fahnestock et al., 2001a). This model invokes the local-layer
 194 approximation (LLA), i.e. it assumes that the time-averaged accumulation rate that the IRH has
 195 experienced since its upstream inception at the surface can be adequately represented by its depth
 196 where it is observed presently. Other 1-D models exist, including the Dansgaard-Johnsen (Dansgaard
 197 and Johnsen, 1969) and the shallow-strain rate model (MacGregor et al., 2016), but were less suitable
 198 for estimating accumulation rates here due to uncertainty in the basal shear layer thickness across our
 199 survey area and because we are limited to only one IRH to constrain the ice-flow model, respectively.
 200 The Nye model assumes that ice thickness is constant and therefore that the ice sheet has been in a
 201 steady state since the deposition of the IRH, an acceptable assumption for the period under
 202 investigation here. The Nye model states:

$$203 \quad \dot{b}_a = \ln\left(\frac{z_a}{H} \frac{H}{a}\right), \quad (1)$$

204 where \dot{b}_a is the mean accumulation rate during the Holocene epoch between an IRH of age a and the
 205 present, z_a represents the depth of the IRH dated at the ice core, and H is the ice thickness. The model
 206 assumes that the vertical strain rate, $\dot{\epsilon}_{zz}^a$, is also constant and vertically uniform, so that it exactly
 207 balances the overburden of local ice accumulation:
 208

$$209 \quad \dot{\epsilon}_{zz}^a = \frac{\dot{b}_a}{H}. \quad (2)$$

209 We iterated Eq. (1) over the re-sampled 500-m spaced dataset using the depth of the 4.72 ka
 210 IRH for z_a and used the median radar-derived ice-thickness measurement re-sampled over the 500-m
 211 grid to obtain H , when this information was available. In areas where the radar did not sound the bed,

212 we used the BedMachine Antarctica v2 gridded product to obtain a value for H (Morlighem, 2020;
213 Morlighem et al., 2020). Note that accumulation rate values presented in this study are all reported in
214 m a^{-1} of ice equivalent using a density value in ice of 917 kg m^{-3} .

215 **2.2.1 Assessing the suitability of the 1-D model**

216 To quantify the suitability of the LLA which is used here to estimate accumulation rates, we
217 calculated the effects of horizontal gradients in modern ice thickness and accumulation rates along
218 particle paths in their ability to affect IRH depths across our grid, as per Waddington et al. (2007).
219 Where these gradients are large, estimates of accumulation rates from IRHs likely require a more
220 complete treatment of ice flow and its effect upon IRH depths, which multi-dimensional models and
221 more physically complete models can better resolve (e.g. Waddington et al., 2007; Leysinger Vieli
222 et al., 2011; Karlsson et al., 2014; Nielsen et al., 2015; Koutnik et al., 2016;). However, such models are
223 significantly more computationally expensive over such a larger area and depend on well-constrained
224 boundary conditions from along-flow radar profiles which are not often available at an ice-sheet level
225 (MacGregor et al., 2009).

226 We quantified the effect of horizontal gradients on an IRH of age a by first estimating the
227 total horizontal particle path length L_{path} each “particle” of the 4.72 ka IRH has travelled since a , and
228 then the characteristic lengths of variability in ice thickness (L_H) and apparent accumulation rate (L_b)
229 (Supplementary Information). These three components were then combined to generate a non-
230 dimensional parameter D (Fig. S1d), which we used as a confidence metric for our inferred
231 accumulation rates. Both Waddington et al. (2007) and MacGregor et al. (2009) suggested a value of
232 $D \ll 1$ over Antarctica, whereas MacGregor et al. (2016) used a maximum value of $D = 1$ to estimate
233 where the LLA is acceptable over Greenland. Because D cannot be translated simply into an
234 uncertainty in an LLA-inferred accumulation rate, it is not yet clear what exact value is appropriate.
235 Smaller values of D indicate that local horizontal gradients in ice thickness and accumulation rates
236 have a smaller effect on IRH depth of age a , and thus that the LLA may be valid (Waddington et al.,
237 2007; MacGregor et al., 2009; 2016). Where $D \geq 1$, the depth of an IRH is less likely to be the result
238 of accumulation rates at the surface or vertical strain rates further down, and thus a more sophisticated
239 model is likely required (Sect. 2.2.2) (Waddington et al., 2007). However, MacGregor et al. (2009)
240 found that even along a flowband across Lake Vostok where the mean value of D is 0.50 for a 41-ka
241 IRH, the difference in accumulation rate inferred from the LLA and from a more sophisticated
242 flowband model could be relatively small (4-16%). This similarly suggests that accumulation rate can
243 be inferred acceptably using the LLA where D is higher.

244 For our study area, D values are mostly well below unity (median: 0.19; 25th quartile: 0.09;
245 75th quartile: 0.34), which suggests relatively little effect from ice-dynamical processes upon IRH
246 depths across most of our grid. We used the upper quartile of the D distribution across our model
247 domain (i.e. $D \leq 0.34$) to show areas where we can have confidence that accumulation rate remains
248 the dominant factor influencing the vertical position of our IRHs in the ice column (i.e. where the
249 $D \ll 1$ criterion is likely met; Fig. S1d). While accumulation rates inferred from IRHs situated in the
250 upper quartile (Fig. S1d) may still be valid, we suggest additional caution in interpreting our results
251 there due to the potential impact of larger flow gradients on IRH depths.

252 **2.2.2 Model limitations and uncertainty**

253 One of the main limitations of the Nye model is that it assumes that gradients in sliding
254 velocity are mostly concentrated in a thin layer at the ice-bed interface and that the ice column
255 deforms by pure shear only (Nye, 1957; Fahnestock et al., 2001a). For this reason, the Nye model is
256 generally only appropriate for IRHs found in the upper part of the ice column, as is the case here.
257 Additionally, the use of the model is restricted to areas where ice flow is relatively slow and
258 horizontal strain rates are also relatively low.

259 Here we focus on a shallower IRH situated in the upper part of the ice column (median: 40%;
260 25th quartile: 30%; 75th quartile: 50%; Fig. 2b-c), for which we can reasonably assume that the ice
261 sheet has remained close to steady state and where IRHs are likely shallow enough not to have
262 experienced appreciable flow disturbances that would affect the Nye model assumptions.
263 Additionally, due to the inherent nature of tracking IRHs through RES data, our coverage is limited to
264 areas where ice-flow speeds are relatively low and IRHs are undisturbed. In some portions of our
265 study area, the IRH is found deeper in the ice column or in faster-flowing sections of the ice sheet
266 (e.g. in the downstream sectors of our grid, Figs. 1 and 2b-c); areas where the assumptions that the 1-
267 D model is based on may be challenged.

268 Estimating uncertainty in accumulation rates from the Nye model is non-trivial. Previous
269 studies have used the misfit between the accumulation rate calculated using multiple proximal IRHs
270 in the ice column (e.g. Fahnestock et al., 2001a; 2001b; Leysinger Vieli et al., 2004; MacGregor et al.,
271 2016). Unfortunately, this method is not suitable here due to the dearth of spatially extensive IRHs
272 younger than 4.72 ka over our model domain.

273 Instead, uncertainty in the Nye-inferred accumulation rates were calculated using: (a) the
274 lowest and highest possible accumulation rates from Eq. (1) using the age uncertainty (± 0.28 ka) of
275 the 4.72 ka IRH and (b) the lowest and highest possible accumulation rates inferred from an additional
276 1-D model (Eq. S5) which accounts for the effect of strain rates on accumulation rates (i.e. the
277 shallow-strain rate model from MacGregor et al. (2016); Supplementary Information; Fig. S2-4).

278 This calculation provides lower and upper bounds for the IRH-inferred accumulation rates
279 (Fig. S4a-b), which were then averaged to generate a relative uncertainty (Fig. S4c). From this
280 assessment, we estimate a median relative uncertainty in the Nye-inferred accumulation rates for the
281 4.72 ka IRH of 14% across our grid. This uncertainty is higher in the downstream edges of our grids,
282 particularly over the PIG, THW and IMIS catchments, and generally low over the Amundsen-
283 Weddell-Ross divide (Fig. S4), reflecting the effect of spatially variable strain rates on the inferred
284 accumulation rates. When combined with the assessment of the suitability of the LLA and exclusion
285 of IRHs where the $D > 1$ (Sect. 2.2.1-2.2.2), we conclude that it supports our application of a 1-D
286 modelling approach here.

287 **2.3 Gridding and filtering**

288 Once IRH depths and accumulation rates for the 4.72 ka IRH were obtained at regular 500-m
289 points along RES flight paths, we filtered the results using a moving-average Gaussian filter of length
290 30 samples (equivalent to ~ 15 km) to reduce along-track noise in the IRH depth. We then gridded the
291 filtered result using a Delaunay-triangulation-based natural neighbour interpolation method onto a 1-
292 km polar stereographic grid. We further smoothed the gridded data using an 18-km square cell mean
293 filter to limit the localised interpolation artefacts in areas of poor survey coverage. Figure S5 shows
294 the maximum distance away from the nearest 500-m along-track point used to produce Figures 2-3,
295 and thus where errors in the interpolated grids are expected to be larger. The median value of this
296 maximum distance is 5 km and its maximum value is 75 km, which is comparable to previous studies
297 that infer SMB from IRHs in the shallow firm (e.g. Medley et al., 2014). We evaluated other possible
298 interpolation methods (e.g. kriging and using different semi-variogram models), but they resulted in
299 similar or poorer quality and were thus discounted.

300 **2.4 Comparison with modern observations**

301 To compare our inferred accumulation estimates for the past 4.72 ka with modern values
302 (defined here as 1651-2019), we derived information on modern accumulation rates from two sources,
303 one modelled (gridded) and one from a series of observational (point-based) datasets.

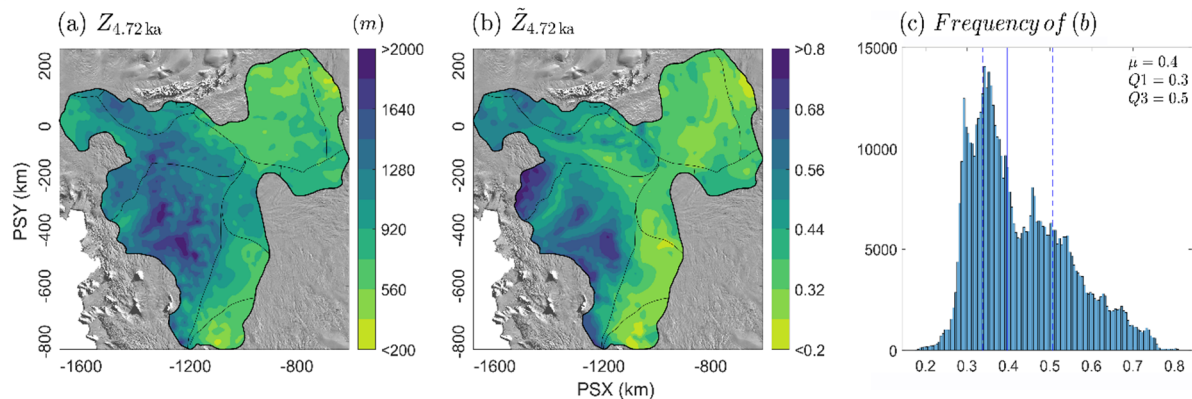

304 We used modelled gridded accumulation rates from the Regional Atmospheric Climate Model
 305 2.3p2 (hereafter RACMO2) 1979-2019 SMB product forced at its margin with the ERA-Interim
 306 product (native resolution: 27 km) as an estimate for modern accumulation rates (Van Wessem et al.,
 307 2018). Although SMB is not technically equivalent to the accumulation rate, runoff and sublimation
 308 are negligible in our survey area (Medley et al., 2013) so we assume SMB is equal to accumulation
 309 rate in this region. We converted modelled values from $\text{kg m}^{-2} \text{a}^{-1}$ to m a^{-1} of ice equivalent using an
 310 ice density value of 917 kg m^{-3} , calculated the 40-year mean, and then bi-linearly interpolated the
 311 gridded RACMO2 product to the same 1-km grid resolution as our 4.72 ka-to-present accumulation
 312 grid (Sect. 2.3) to ensure consistency when comparing both datasets.

313 Observational point-based measurements were obtained from a series of snow, firn and ice
 314 cores from the ITASE (Mayewski and Dixon, 2013), MED14 (Medley et al., 2014), SAMBA (Favier
 315 et al., 2013), and SEAT-10 (Burgener et al., 2013) datasets, as well as from a network of centennially-
 316 averaged modern accumulation rates derived from shallow IRHs traced on ground-based RES data
 317 over the central divide and dated using a shallow ITASE Ice Core (Neumann et al., 2008) (Fig. 1).
 318 This resulted in 79 point-based accumulation measurements from cores covering the period 1651-
 319 2010 CE (Common Era) and spread across our model domain (see Figure 1). Further detail on these
 320 datasets can be found in the above references.

321 To compare the Holocene gridded product with the point-based measurements, we first
 322 calculated the average value of the accumulation rate at the point measurement for the entire period.
 323 We converted these values to ice-equivalent accumulation rates and then extracted two paired values,
 324 i.e. the value for the point-measurement for modern accumulation rates and the value for the nearest
 325 grid cell in the gridded 4.72 ka-to-present accumulation estimates to this measurement.

326 Results

327 The final grids for depth and accumulation rates for the 4.72 ka IRH are shown in Figures 2 and 3.
 328 In total, these grids are made of $\sim 89\,000$, 500-m spaced points, which cover an area of $\sim 610\,000 \text{ km}^2$,
 329 or $\sim 30\%$ of the total surface area of the WAIS. The grids span most of the PIG and THW glacier
 330 catchments, as well as the Ronne (upper Rutford, Institute, and Möller) and upper western Ross
 331 (Bindschadler, Kamb, MacAyeal, and Whillans) catchments (IPY Antarctic boundaries G-H, J-Jpp,
 332 and Ep-F; Mouginito et al. (2017); Fig. 1-2). Overall, the 4.72 ka IRH is shallower within the IMIS
 333 and upper PIG and THW catchments, as well as on the Ross side of the central divide where ice
 334 thickness is particularly deep (Fig. 2b). Conversely, the 4.72 ka IRH is deeper in the ice near a 400-m
 335 high bedrock plateau that separates the northern and southern basins of PIG (Vaughan et al., 2006)
 336 and at two locations in the upstream parts of the main trunk of THW where ice flows over highs in
 337 subglacial topography (Fig. 2b).

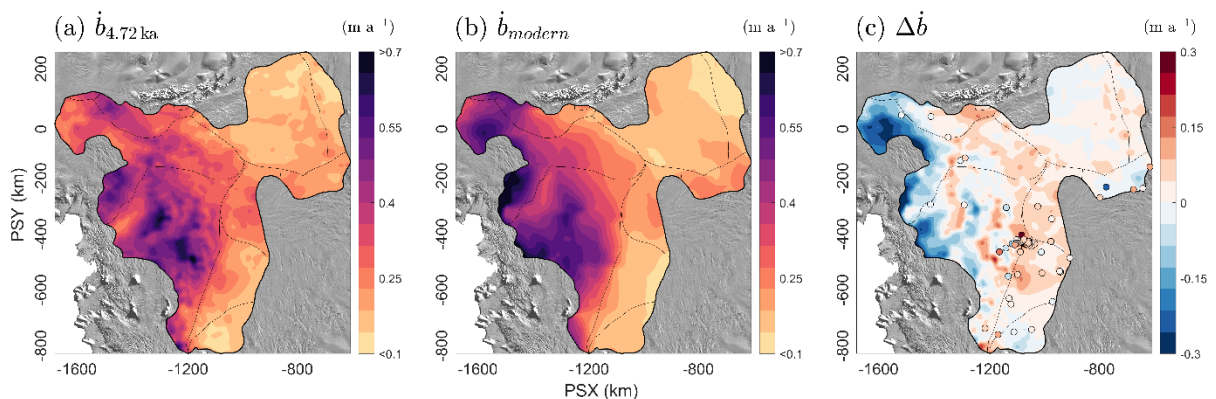

338

339 Figure 2. Gridded depths for the 4.72 ka IRH across the model domain covering the PIG, THW, and
 340 Institute and Möller ice-stream catchments. (a) Gridded depth of the 4.72 ka IRH. (b) Normalised depth of the

341 4.72 ka IRH relative to ice thickness. (c) Histogram showing the distribution of values in (b) with the median ($\bar{\mu}$)
 342 and interquartile range (i.e. 25th (Q1) and 75th (Q3) quartiles) shown as solid and dashed blue lines respectively.
 343 The background image is the 2014 MODIS mosaic of Antarctica (Haran et al., 2018).

344 3.1. Catchment-scale accumulation estimates

345 Figure 3 shows a comparison of the ice-equivalent accumulation rates we inferred for the 4.72
 346 ka IRH (Fig. 3a) and modern SMB estimates from RACMO2 (Fig. 3b). We observe that the IRH
 347 accumulation rate pattern for the last 4.72 ka is similar to the modern pattern of accumulation rates for
 348 the Amundsen Sea sector of the WAIS, which is dominated by higher coastal accumulation rates that
 349 progressively decrease inland to reach their lowest rates over the Ross side of the divide (Fig. 3a-b).
 350 Differences in accumulation rates between the 4.72 ka-to-present estimates and modern values are
 351 mainly observed directly upstream of the main trunks of PIG and THW, where modern rates are much
 352 higher (up to 0.2 m a^{-1} ice equivalent) than for the 4.72 ka-to-present estimates (Fig. 3c). In
 353 comparison, higher accumulation rates for the last 4.72 ka relative to modern rates are observed for
 354 the entire stretch of the Amundsen-Weddell-Ross divide (Fig. 3c; Table 2). Over the IMIS catchment,
 355 little change is observed between the two periods. Over the entire model domain, we observe a
 356 median percentage change value of 6% higher accumulation since 4.72 ka compared with modern
 357 rates (Fig. 4); however, when considering only the values that fall within 100 km of either side of the
 358 Amundsen-Weddell-Ross divide (i.e. in the accumulation zone of the Amundsen, Weddell, and Ross
 359 Sea sectors and where mean surface speeds average $\sim 7 \text{ m a}^{-1}$), we obtain a median percentage change
 360 value of 18% higher accumulation compared with modern accumulation rates (Fig. 4).

361
 362 Figure 3. Gridded estimates of ice-equivalent accumulation rates for the last 4.72 ka and modern times.
 363 (a) Gridded accumulation rates inferred from the 4.72 ka IRH. (b) Modern (1979 – 2019) modelled SMB rates
 364 from RACMO2. (c) Difference between 4.72 ka-to-present and modern accumulation rates (red = 4.72 ka-to-
 365 present accumulation higher than modern times, blue = 4.72 ka-to-present accumulation lower than modern
 366 times). The dots represent the difference between the value for the nearest grid cell in (a) and time-averaged
 367 accumulation rates at each of the 79 core locations (see Section 2.4; Fig. S6). The background image is the 2014
 368 MODIS mosaic of Antarctica (Haran et al., 2018).

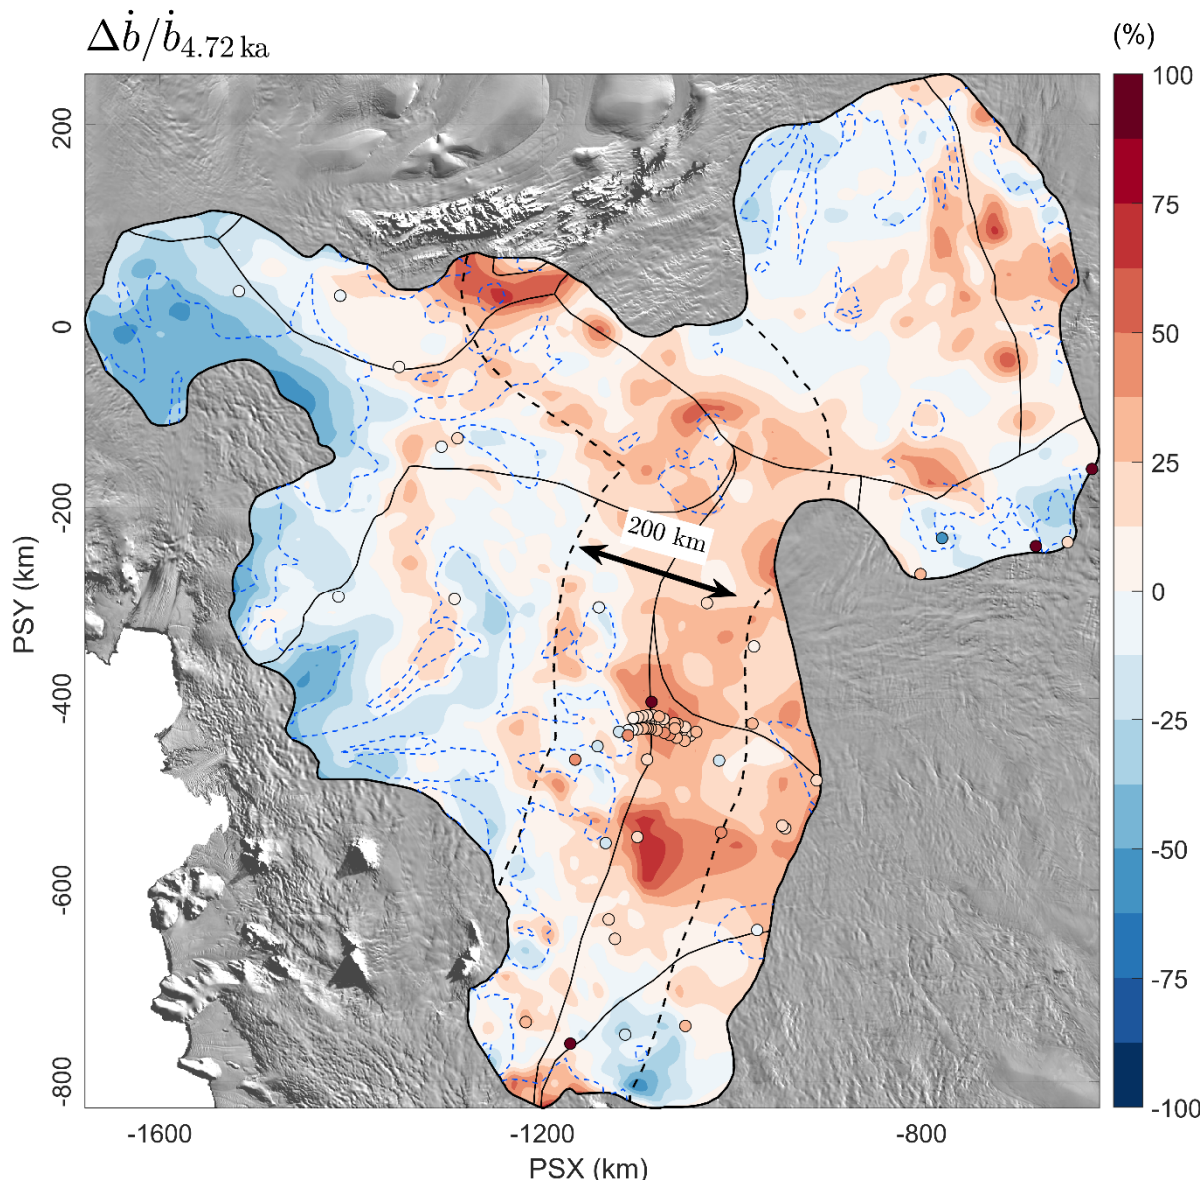

369 Comparison between our 4.72 ka-to-present accumulation-rate estimates and 79 core-derived
 370 point-based accumulation measurements for modern times (1651-2010 CE) are shown in Figures 3-4
 371 and S6. This evaluation shows that the 4.72 ka-to-present accumulation-rate estimates for the nearest
 372 grid cell to each point measurement are, on average, 22% higher for cores situated across the entire
 373 grid ($p < .0015, n=79$) and 23% higher for cores found within 100 km of the divide compared with
 374 modern accumulation rates ($p < .0001, n=59$; Figs. 4 and S6). In comparison, a similar analysis
 375 between grid cells from the 4.72 ka-to-present accumulation-rate estimates and RACMO2 at these 79
 376 core locations shows mid-Holocene accumulation rate estimates are, on average, 32% ($P < .00002,$
 377 $n=79$) higher for cores situated across the entire grid and 36% higher for cores found within 100 km
 378 of the divide ($p < .00001, n=59$; Fig. S6). This result confirms that the relative change for gridded

379 accumulation rates between the 4.72 ka-to-present and modern modelled accumulation rates is
 380 consistent with modern rates from point-based measurements.

381 Table 2. Summary statistics for the modern (modelled and observational) and 4.72 ka-to-present ice-
 382 equivalent accumulation rates at the catchment-scale and over the Amundsen-Weddell-Ross divide (abbreviated
 383 CD for Central Divide here). Values for the Amundsen-Weddell-Ross divide are for all points that fall within
 384 100 km of either side of the divide (see dashed line in Figure 4). $\tilde{\mu}$ refers to the median and IQR represents the
 385 Interquartile Range calculated by computing the difference between the 75th and 25th percentiles. Note that the
 386 values provided in the text represent the median relative change from the cell-by-cell change between each grid
 387 (Fig. 4), rather than the relative change of the median values provided here.

Accumulation rate ($m a^{-1}$)	Catchment-wide		CD only	
	$\tilde{\mu}$	IQR	$\tilde{\mu}$	IQR
Modern (model)	0.23	0.23	0.22	0.10
Modern (cores)	0.24	0.12	0.24	0.09
4.72 ka-to-present	0.27	0.18	0.27	0.11

388

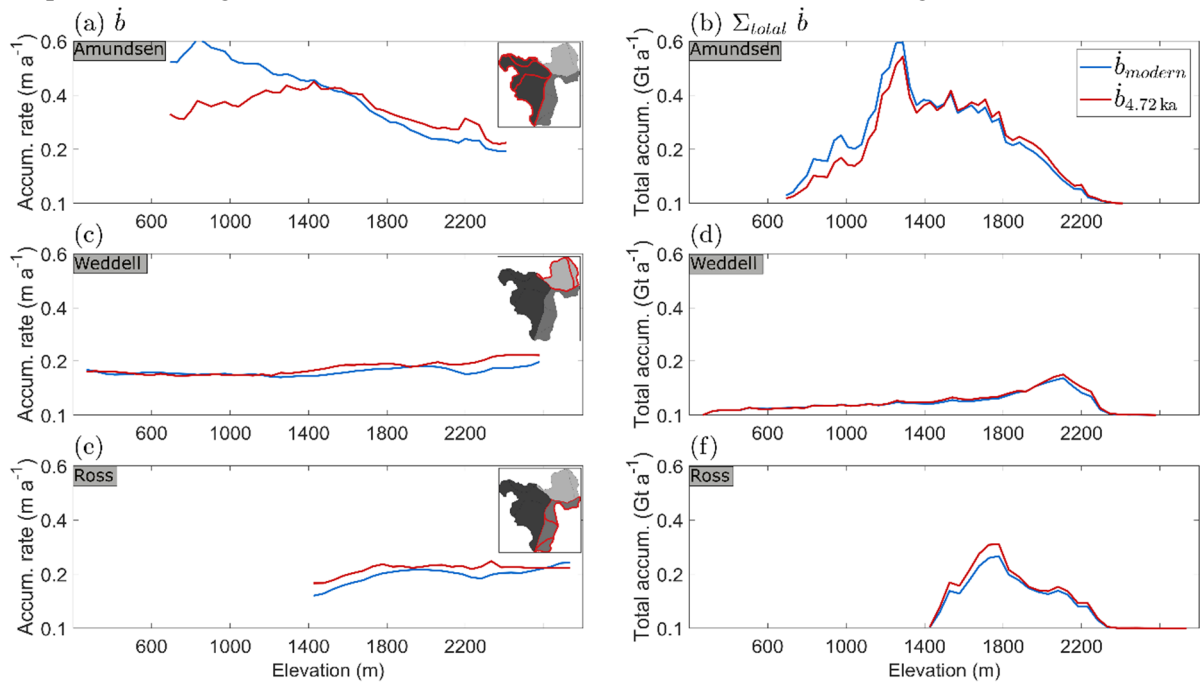

389

390 Figure 4. Relative change in accumulation rates between the 4.72 ka-to-present estimates and modern
 391 rates. The points on the map represent the relative change in ice-equivalent accumulation rate between the
 392 nearest grid cell in the 4.72 ka-to-present grid and the 79 modern observations from cores (Figs. 1 and S6; Sect.
 393 2.4). The dashed black outline line represents the 100-km boundary on either side of the Amundsen-Weddell-
 394 Ross divide used to provide the summary statistics in Section 3.1 and Table 2. The dashed blue line shows the
 395 contours of the upper limit of the interquartile range for the D parameter ($D \leq 0.34$), whereby all values situated
 396 inside of this boundary may satisfy the $D \ll 1$ criteria and those outside may require re-evaluating with the use
 397 of multi-dimensional models (Sect. 2.2.1-2.2.2). The background image is the 2014 MODIS mosaic of
 398 Antarctica (Haran et al., 2018).

399 3.2 Elevation-dependent accumulation estimates

400 While Figures 3 and 4 help to assess potential differences in patterns and rates across spatial
 401 scales, considering accumulation-rate differences in terms of elevation can inform how topography
 402 influences accumulation and whether this has changed over time. We binned the ice-equivalent
 403 accumulation values by 50-m elevation bands across the three main catchments covering our grid
 404 (Amundsen, Weddell and Ross) for both the 4.72 ka-to-present estimates and modern model rates and
 405 calculated the mean accumulation rate and the total accumulation rate for each bin over the entire
 406 elevation gradient (Fig. 5). We again find that the accumulation-rate estimates for the period since
 407 4.72 ka are lower at low elevations ($\sim 700 - 1400$ m) over the Amundsen sector compared with
 408 RACMO2, but begin to exceed RACMO2 near the 1400-m elevation band where the 4.72 ka-to-
 409 present accumulation rate is higher than modern times across the divide (Fig. 5a-b). We also note that
 410 whilst an elevation-dependent gradient in accumulation rates, dominated by high accumulation at the
 411 coast decreasing inland, exists over this sector for the mid-Holocene, it is much less marked than for
 412 present rates. This is not surprising, as this sector is where we observe the largest relative
 413 uncertainties in inferred accumulation rates across our grid (Fig. S4), indicating that the 1-D model is
 414 less able to produce realistic accumulation rates in the downstream end of our grid where ice flow is
 415 faster and strain rates are likely higher. In comparison to the Amundsen sector, accumulation rates
 416 since 4.72 ka are generally higher at all elevations for the Weddell and Ross sectors compared with
 417 the present, although this difference is less than over the Amundsen sector (Fig. 5 c-f).

418

419 Figure 5. Comparison of ice-equivalent accumulation rates between the 4.72 ka-to-present estimates and
 420 modern rates (RACMO2) binned by 50-m elevation bands across the three main catchments considered here
 421 (Amundsen, Weddell, and Ross). (a, c, e) Mean accumulation rate averaged per 50-m elevation band across the

422 specific catchment area in m a^{-1} . (b, d, f) Total accumulation rate per 50-m elevation band across the specific
423 catchment area in Gigatonnes per annum (Gt a^{-1}).

424 **4. Discussion**

425 **4.1. Comparison with other Holocene accumulation estimates**

426 Previous studies of past accumulation rates over the WAIS have shown that accumulation varied
427 temporally during the Holocene. Using a single airborne RES profile over the Amundsen Sea sector,
428 Siegert and Payne (2004) showed that accumulation rates were approximately the same at 3.1 ka
429 compared with modern rates, but $\sim 0.3 \text{ m a}^{-1}$ greater ($\sim 15\%$) than current rates between 3.1-6.4 ka,
430 before which accumulation was $\sim 50\%$ of modern rates between 6.4 and 16.0 ka. Similarly, Neumann
431 et al. (2008) found that accumulation rates at the Amundsen-Weddell-Ross divide were $\sim 30\%$ higher
432 between 3-5 ka than modern values based on a dense network of IRHs traced on ground-based RES
433 data, while Karlsson et al. (2014) found that accumulation patterns had likely changed twice during
434 the early to mid-Holocene over PIG from the lack of a model fit between the depths and ages of two
435 prominent IRHs. Using the updated WD14 record, Fudge et al. (2016) showed that accumulation rates
436 were higher there in the mid to late-Holocene (19% between 4.72 ka BP and the present), a trend that
437 was also observed by Koutnik et al. (2016), who found a 20% increase in accumulation rates between
438 2-4 ka compared with modern rates from a ground-based RES profile across the ice divide.

439 These studies together point to a period of increasing accumulation observed at the WD14 Ice
440 Core from ~ 7 ka onwards (Fudge et al., 2016; their Figure 2), with its peak matching the age of the
441 4.72 ka IRH used here. Thus, our accumulation-rate estimates likely form part of a wider pattern of a
442 sustained increase in accumulation across the Amundsen-Weddell-Ross divide over several millennia.
443 In showing that mean accumulation rates since 4.72 ka were 18% greater than modern rates modelled
444 from RACMO2 across the Amundsen-Weddell-Ross divide, our results provide much wider regional
445 support for the hypothesis that accumulation rates during the mid-Holocene exceeded modern rates
446 across central West Antarctica. A possible explanation for the higher accumulation rates during the
447 mid-Holocene compared with modern values is that they represent a continued climatic transition
448 from the LGM (Steig et al., 2001). Alternatively, it has been suggested that seasonal or interannual
449 variability, such as a weaker circumpolar vortex (van Den Broeke and van Lipzig, 2004; Neumann et
450 al., 2008), or teleconnections to tropical Pacific Ocean warming (Sproson et al., 2022), may also lead
451 to such difference. We did not find evidence for significant changes in accumulation patterns between
452 the mid-Holocene and modern times, suggesting that the current spatial pattern of high accumulation
453 on the Amundsen side of the divide transitioning to low accumulation on the Ross side of the divide
454 was stable throughout the mid-Holocene, as previously suggested by others (Siegert and Payne, 2004;
455 Neumann et al., 2008; Koutnik et al., 2016).

456 We also find that accumulation estimates for the 4.72 ka-to-present are smaller than modern rates
457 in the lowest elevation bands (< 1400 m), particularly over the Amundsen Sector (Fig. 5 a-d). This
458 pattern was also found by Medley et al. (2014), who compared modern observational and modelled
459 data over this sector and hypothesised that this discrepancy at low elevations resulted primarily from a
460 lack of sufficient accumulation measurements in the lower sections of their survey area. In our case,
461 these low-elevation values are close to the boundary where we consider the LLA acceptable for the
462 4.72 ka IRH, albeit where D values are higher than for the rest of the catchment (Figure S1d), so it is
463 more likely that accumulation rates calculated there are affected by ice-flow gradients and their
464 influence upon IRH depths leading to lower accumulation rates there. Despite this caveat, Figures 5b
465 and 5d show that values at low elevations contribute relatively little to the total accumulation (by
466 mass) over our survey area.

467 We suggest that future ice-sheet modelling studies investigate the difference in accumulation rates
468 inferred from our 1-D model using multi-dimensional flowband models to assess effects of divergent

469 and convergent flow on IRH depth and ultimately accumulation rates, as previously considered
470 elsewhere in Antarctica (MacGregor et al., 2009). This could be conducted along a flowline
471 transitioning from the slow-flowing regions directly downstream of the Amundsen-Weddell-Ross
472 divide to the coastal margins of our grid, particularly over THW where we observe the largest
473 uncertainties in accumulation rates. In addition, we suggest that future modelling studies use the
474 accumulation-rate variability from the WD14 Ice Core as a climate forcing in their ice-sheet models.
475 Koutnik et al. (2016) previously showed that the WD14 record is unique in that it provides a reliable
476 record of accumulation-rate variability during the Holocene, which other East Antarctic ice-core
477 records often used to reconstruct the evolution of the WAIS do not possess. We found that these
478 higher accumulation rates are spatially extensive across nearly one third of the WAIS, further
479 suggesting that the WD14 Ice Core is indeed representative of the wider WAIS and can be used in
480 regional or continental ice-sheet models as a reliable climate forcing for the region. Future regional
481 and continental ice-sheet models should make use of this record to adjust their climatic boundary
482 conditions to provide improved estimates of ice-elevation change and grounding-line evolution over
483 Antarctica.

484 **4.2 Impact for ice-sheet elevation change during the Holocene**

485 Model results from Steig et al. (2001) suggest that the maximum elevation of the WAIS was most
486 likely reached during the early to mid-Holocene (around ~7 ka) following higher accumulation rates
487 at the late glacial–interglacial transition, after which the WAIS slowly declined to present conditions
488 as the sea-level-rise-induced kinematic wave reached the ice-sheet interior and outpaced the increase
489 in accumulation rates. However, higher accumulation rates in the mid-Holocene relative to the
490 present, which our results suggest occurred spatially across the WAIS, would likely delay the timing
491 of this thinning by several thousand years (Steig et al., 2011).

492 Using a flowband model, Koutnik et al. (2016) suggested that an increase of up to 40% in
493 accumulation rates for the period 9 – 2 ka would likely have led to an increase in ice thickness of tens
494 of metres during the mid-Holocene. Although this finding was warranted by physical assumptions
495 around the response time of the ice-sheet interior to adjust to an increase in accumulation in the
496 model, it points to the potential for the divide to have thickened by several metres over a relatively
497 short period of time from increased accumulation rates alone. Because the WAIS is also sensitive to
498 ice-dynamical changes at the ice-sheet margins (e.g. grounding-line retreat or calving), an increase in
499 accumulation rates in the upper part of the ice sheet may not necessarily result in enough thickening to
500 counteract potential dynamical losses farther downstream (Jones et al., 2022). Conway and
501 Rasmussen (2008) reported that the Amundsen-Ross Divide is currently thinning and migrating
502 towards the Ross Sea at a speed of 10 m a⁻¹, but they were unable to determine whether this was in
503 response to long-term (last two millennia) accumulation-rate changes there or short-term (last few
504 centuries) ice-dynamical forcing from the coastal margins of the Amundsen and Ross sectors. More
505 recently, Balco et al. (2023) showed that Thwaites and Pope glaciers experienced 35 m of thickening
506 in the mid-to-late Holocene, when accumulation rates were higher than present. While this thickening
507 relative to present was attributed to glacio-isostatic rebound, it is also possible that higher
508 accumulation rates in the upstream sections of the WAIS contributed to this thickening, if sustained
509 over millennia.

510 The lack of an ice-dynamical component in the model used here precludes us from evaluating
511 any ice-surface-elevation change associated with changing accumulation rates. However, 18% higher
512 accumulation rates during the mid-Holocene relative to the present across 30% of the WAIS could be
513 consistent with an elevation increase of several tens of metres in ice thickness, according to Koutnik
514 et al. (2016). Even if tens of metres of ice-surface-elevation change occurred, it is still unlikely to
515 significantly affect the steady-state assumption of the 1-D model used here (constant ice thickness

516 over time), because such changes are small (a few per cent of the ice thickness) and that ice thickness
517 exceeds 3500 m in places over our survey area.

518 **4.3 Impact for grounding-line evolution during the Holocene over the WAIS**

519 Finally, we consider the possibility for Holocene ice thickening at the divide from increased
520 accumulation rates to affect downstream grounding-line evolution. Recent evidence from ice-sheet
521 modelling and field measurements suggest that grounding-line retreat during the Holocene was not
522 monotonic, particularly at the Ross and Weddell Sea sides of the WAIS (Bradley et al., 2015;
523 Kingslake et al., 2018; Neuhaus et al., 2021). Rather, Kingslake et al. (2018) showed that the
524 grounding-line position in the Ross and Weddell Sea sectors initially retreated from the LGM inland
525 until ~10.2 – 9.7 ka, and then readvanced to its modern position sometime during the Holocene.
526 Although they attributed this change in grounding-line position to the solid Earth viscoelastic
527 response due to ice-sheet mass change and the subsequent re-grounding around pinning points, it has
528 also been suggested that an increase in accumulation rates upstream of the grounding line could lead
529 to a readvance via ice thickening there and a subsequent increase in ice flow (Steig et al., 2001;
530 Koutnik et al., 2016; Jones et al., 2022). Across parts of the Weddell Sea Embayment, several studies
531 have produced evidence for stability of the LGM ice thickness there until the early to mid-Holocene
532 (Ross et al., 2011; Hein et al., 2016; Ashmore et al., 2020a), contrary to most of the WAIS, after
533 which abrupt thinning of ~400 m contributed ~1.4 – 2 m of sea level rise (Hein et al., 2016). A
534 possible explanation for this delayed thinning in the Weddell Sea Embayment is that increased
535 snowfall in the upper WAIS might have counteracted ice-dynamical processes at the coast until the
536 mid-to-late Holocene (Hein et al., 2016; Spector et al., 2019). Similarly, over part of the Ross Sea
537 sector, Neuhaus et al. (2021) showed that the grounding line over Whillans, Kamb, and Bindschadler
538 ice streams retreated to its minimum Holocene position in the mid to late-Holocene, and then
539 readvanced between 2 – 1 ka, coinciding with periods of warmer and colder climates, respectively.
540 They concluded that the reported grounding-line migration was likely dominated by modest climate-
541 induced changes upstream rather than ice dynamics further downstream, as suggested for the Weddell
542 Sea sector (Hein et al., 2016).

543 Our results, which provide strong and widespread evidence for higher accumulation along the
544 Amundsen-Weddell-Ross divide during the mid-Holocene compared with the present, support these
545 hypotheses further, as higher accumulation rates at the divide would likely result in upstream
546 thickening (Sect. 4.2). In the absence of ice-dynamical processes counter-balancing this increase in
547 accumulation rates, the grounding-line should advance in these regions. However, we note that the
548 pattern of grounding-line retreat and readvance has not been observed over the Amundsen Sea sector
549 (Kingslake et al., 2018; Johnson et al., 2020; 2021; Braddock et al., 2022) despite the accumulation-
550 rate increase we also observed along the Amundsen-Weddell-Ross divide and the recent results from
551 Balco et al. (2023). This complication may indicate that the Amundsen sector is more strongly
552 influenced by coastal changes in ice dynamics, for which even moderate changes in accumulation rate
553 cannot compensate.

554 **5. Conclusion**

555 Using a ubiquitous internal reflecting horizon found across most of the Pine Island, Thwaites, and
556 Institute and Möller ice-stream catchments, we have estimated mid-Holocene accumulation rates in
557 the relatively slow-flowing parts of West Antarctica, representing 30% of total surface area of the
558 WAIS.

559 By comparing our Holocene accumulation-rate estimates with a modern climate reanalysis model
560 and observational syntheses, we estimated that accumulation rates across the Amundsen-Weddell-
561 Ross Sea divide since 4.72 ka were, on average, 18% higher than modern values. Our results suggest
562 that spatial patterns of accumulation across the WAIS have remained stable during this period, i.e.

563 higher accumulation rates on the Amundsen side of the divide transitioning to lower accumulation
564 rates on the Ross side of the divide. The higher accumulation rates reported here for the mid-Holocene
565 compared to the present agree well with earlier, spatially-focused studies of accumulation rates, all of
566 which indicate higher accumulation rates (+15 - 30%) over the past ~5 ka. This change in magnitude
567 occurred at a time of asynchronous grounding-line migration over the WAIS, including readvances of
568 the grounding line in the Weddell and Ross sectors and evidence for delayed deglaciation in the
569 Weddell Sea side of the WAIS.

570 The higher mid-Holocene accumulation estimates inferred here over large sectors of the WAIS
571 occurred at a time of sustained, millennial-scale increase in accumulation rates found at the WAIS
572 Divide Ice Core. This pattern indicates that the ice core is suitably representative of the climatic
573 conditions of the wider region over time. We suggest that future regional or continental ice-sheet
574 modelling studies base their palaeoclimate forcing on modern spatial SMB products that are
575 modulated over time using the WAIS Divide Ice Core record. This will enable those models to obtain
576 a more realistic climatic forcing representative of the past conditions of the wider WAIS, and
577 ultimately, constrain ice-sheet volume change and grounding-line evolution during the Holocene.

578 **Code availability**

579 All the codes used to produce the results presented in this paper are available on the GitHub
580 page of Julien A. Bodart (<https://github.com/julbod>, last accessed: 15 March 2023) and on Zenodo
581 (Bodart et al., 2023).

582 **Data availability**

583 The IRH information for each of the three surveys used in this paper are archived in open-
584 access repositories (Ashmore et al., 2020b; Bodart et al., 2021b; Muldoon et al., 2023) with references
585 and links provided in the reference list. The BAS airborne radar data which were used to extract the
586 IRHs used in this paper are fully available at the UK Polar Data Centre via the Polar Airborne
587 Geophysics Data Portal (see Frémand, Bodart et al., 2022). The RACMO2 product is available on
588 request from j.m.vanwessem@uu.nl or m.r.vandenbroeke@uu.nl. Links to access the observational
589 point-based datasets used here are available from the respective references mentioned in the text
590 (Section 2.4). The gridded depth and accumulation output from this study are archived on Zenodo
591 (Bodart et al., 2023).

592 **Author contribution**

593 J.A.B. designed the study with supervision from R.G.B., D.A.Y., and D.D.B. J.A.B.
594 performed the data processing, gridding, and 1-D modelling, with contributions from J.A.M. for the
595 modelling approach. J.A.B. interpreted the results with input from R.G.B., D.A.Y., D.D.B., and
596 J.A.M. J.A.B. wrote the paper, with edits from R.G.B., D.A.Y., J.A.M., D.W.A., E.Q., A.S.H.,
597 D.G.V., D.D.B.

598 **Competing interests**

599 The authors declare that they have no conflict of interest.

600 **Acknowledgments**

601 The authors would like to dedicate this work to our dear friend and colleague, Professor
602 David Vaughan, who recently passed away. This study was motivated by the AntArchitecture SCAR
603 Action Group. UTIG acknowledges the high school students who did the original AGASEA layer
604 interpretation. We would like to thank the editor, Olaf Eisen, as well as Michelle Koutnik and an
605 anonymous reviewers for thorough and constructive reviews, which improved this manuscript.

606 **Financial support**

607 J.A.B. was supported by the NERC Doctoral Training Partnership grant (NE/L002558/1),
608 hosted in the Edinburgh E³ DTP programme. J.A.B. also acknowledges the Scottish Alliance for
609 Geoscience, Environment and Society (SAGES) for funding a Postdoctoral and Early Career
610 Researcher Exchanges scheme to UTIG. Support for UTIG data analysis was received from NSF
611 grant nos CDI-0941678, PLR-1443690, and PLR-10437661, as well as the G. Unger Vetlesen
612 Foundation and the UTIG Gale White and Ewing/Worzel Fellowships. This is UTIG contribution No.
613 XXX (TBD) and ITGC Contribution No. XXX (TBD).
