Abstract. Clouds are an important component of the climate system, yet our understanding of how they directly and indirectly affect glacier melt in different climates is incomplete. Here we analyse high-quality datasets from 16 mountain glaciers in
25 diverse climates around the globe to better understand how relationships between clouds and near-surface meteorology, radiation, and surface energy balance vary. The seasonal cycle of cloud frequency varies markedly between mountain glacier sites. During the main melt season at each site, an increase in cloud cover is associated with increased vapour pressure and relative humidity but relationships to wind speed are site-specific. At colder sites (average near-surface air temperature in melt season < 0 °C), air temperature generally increases with increasing cloudiness, while for warmer sites (average near-surface
30 air temperature in melt season $\gg 0$ °C) air temperature decreases with increasing cloudiness. At all sites, surface melt is more frequent in cloudy compared to clear-sky conditions. The proportion of melt from temperature-dependent energy fluxes (incoming longwave radiation, turbulent sensible and latent heat) also universally increases in cloudy conditions. However, cloud cover does not affect daily total melt in a universal way, with some sites showing increased melt energy during cloudy conditions and others decreased melt energy. The complex association of clouds with melt energy is not amenable to simple

35 relationships due to many interacting physical processes (varies with latitude, average melt-season air temperature, continentality, season, and elevation) but is most closely related to the effect of clouds on net radiation. These results motivate the use of physics-based surface energy balance models for representing glacier-climate relationships in regional- and global-scale assessments of glacier response to climate change.

1 Introduction

40 Mountain glaciers are sensitive and important components of the climate system. Over the last 50 years, mountain glacier melt has contributed 36-40% of the observed global sea level rise (Hock et al., 2009; Church et al., 2011; Mernild et al., 2014; Zemp et al., 2019; Hugonnet et al., 2021). During the rest of the 21st century, a large but uncertain fraction of the remaining mass stored in mountain glaciers is expected to melt (Radić et al., 2014; Kraaijenbrink et al., 2017; Marzeion et al., 2018; Huss and Hock, 2018; Zekollari et al., 2019). As glaciers are sensitive to change in their surrounding climate, they can be used to infer
45 past changes in climate over decadal (e.g. Mackintosh et al., 2017), centennial (e.g. Oerlemans, 2005; Mölg et al., 2009b) and paleo-climatic timescales (e.g. Putnam et al., 2012).

Our ability to determine how mountain glacier melt responds to changes in climate depends on the ability of models to correctly represent the processes that occur at the atmosphere-glacier interface and link near-surface meteorology and surface melt. The
50 surface energy balance (SEB) is the key process that controls the rate of melt at the glacier surface and can be represented as:

$$Q_M = SW_{net} + LW_{net} + Q_S + Q_L + Q_C + Q_{PRC} \quad 1$$

where Q_M is the energy available for melt (zero when surface is freezing), SW_{net} and LW_{net} are the net fluxes of short and
55 long-wave radiation (including shortwave radiation that penetrates the surface), Q_S and Q_L are the turbulent fluxes of sensible and latent heat, Q_C is the conductive heat flux into/out of the glacier subsurface and Q_{PRC} is the heat advected from precipitation. Fluxes on the righthand side of Equation 1 are defined as positive towards the surface. When the surface is at the melting point, Q_M becomes non-zero and positive, and surface melt (M , mm w.e.) is determined through:

$$60 \quad M = Q_M * \Delta t / L_f \quad 2$$

where Δt is the timestep of model output (seconds) and L_f is the latent heat of fusion ($3.34 \times 10^5 \text{ J kg}^{-1}$). In many studies, these relationships between near-surface meteorology and melt are simplified into parameterisations that require less input data such as temperature index or enhanced temperature index melt models (Huybrechts and Oerlemans, 1990; Hock, 2003; Pellicciotti
65 et al., 2005)

While we know that glaciers are sensitive to changes in local climate, the extent to which cloud cover will amplify or reduce the melting of a glacier in response to future atmospheric warming is uncertain. Clouds alter the incoming shortwave (*SWin*) and longwave (*LWin*) radiation, which are generally the largest sources of energy at the glacier surface (Sicart et al., 2008; Pellicciotti et al., 2011; Van Den Broeke et al., 2011; Cullen and Conway, 2015). Over highly reflective glacier surfaces, a ‘radiation paradox’ can occur, where net radiation (*Rnet*) increases during cloudy conditions (Ambach, 1974). Clouds can also enhance or dampen the influence of near-surface meteorology, albedo feedbacks and subsurface processes (e.g. refreezing) on SEB and melt (Giesen et al., 2008; Giesen et al., 2014; Conway and Cullen, 2016; Van Tricht et al., 2016). As a result, clouds have been associated with both increased and decreased melt rate depending on the climate (Van Den Broeke et al., 2011; Conway and Cullen, 2016; Chen et al., 2021). In the maritime Southern Alps of New Zealand, cloudy conditions have been shown to increase the sensitivity of melt to changes in air temperature (Conway and Cullen, 2016), due to: (i) more frequent melt in cloudy compared to clear-sky conditions, (ii) increased (positive) *LWnet* and Q_L in cloudy conditions that enable a similar daily melt rate as clear-sky conditions, and (iii) a change in precipitation phase (from snow to rain) that enhances a positive snowdepth - albedo feedback. The higher sensitivity in cloudy conditions implies that, in the Southern Alps, the response of glacier melt (as well as accumulation) to past and future atmospheric warming will be modulated by atmospheric moisture (in the form of vapour/cloud/precipitation). How these processes interact in different mountain glacier environments and climate regimes has not been well established.

One challenge has been the lack of direct measurements of cloud amount or type (from e.g. human observer, all-sky camera, or ceilometer) in mountain areas, which has required the derivation of cloud metrics from surface radiation measurements. Studies have employed a variety of methods to derive cloudiness from surface radiation measurements, which limits the ability to directly compare results from studies in different regions (Giesen et al., 2008; Conway and Cullen, 2016; Sicart et al., 2016; Chen et al., 2021).

The key question of this paper is, therefore: how does cloudiness and its relationships with near-surface meteorology, radiation, and energy balance vary in different mountain glacier environments? The objective is to use a common framework to assess these relationships at a diverse set of sites where high-quality observations and modelling are available. To guide the analyses, a set of questions was posed:

- i. How often do different cloud conditions occur at each site?
- ii. What is the direct effect of clouds on surface radiation at each site?
- iii. How does near-surface meteorology vary with cloudiness?
- iv. How do the characteristics of melt (e.g. frequency, amount and source of energy) vary in different cloud conditions?

Section 2 sets out the methods used to collate and analyse data sets from 16 glacier AWS sites, including the calculation of cloudiness from *LWin*, the definition of melting periods and melt season, and analysis of cloud effects. Section 3 presents

results that address the four questions posed above. Section 4 discusses commonalities and differences in cloud – meteorology – SEB – melt relationships, uncertainties and implications for glacier melt modelling.

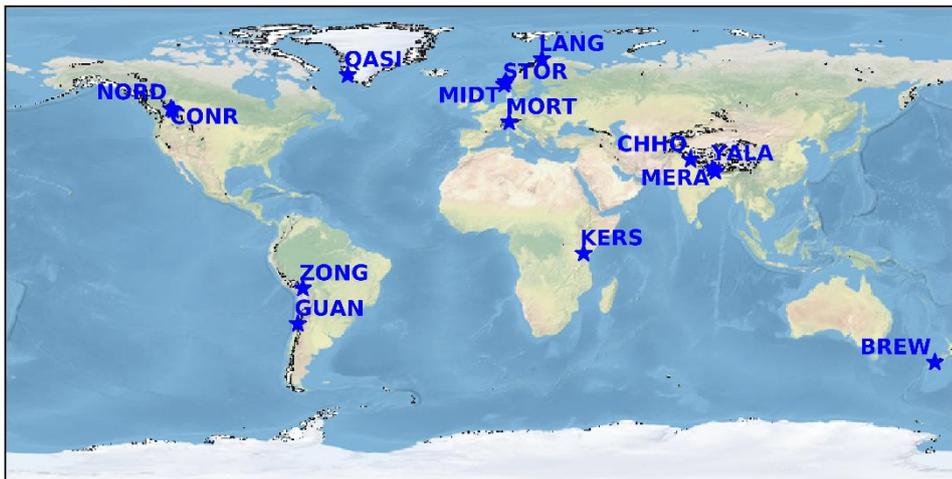

2 Methods

2.1 Sites and dataset requirements

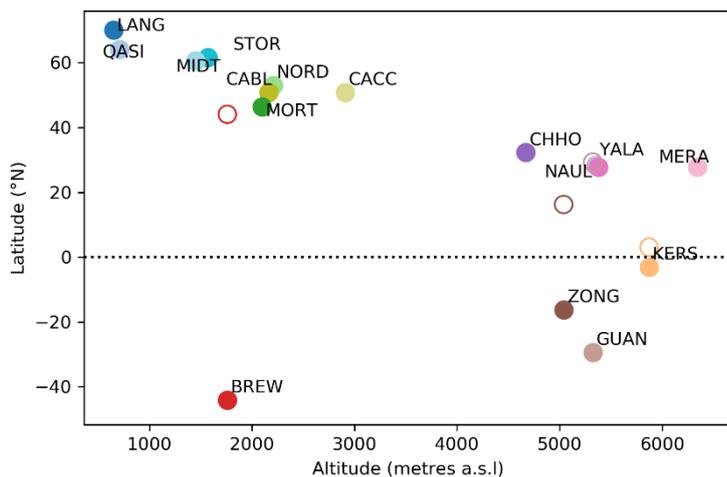

105 Datasets of near-surface meteorology and glacier surface energy balance were collated from a diverse set of sites where high-quality observations and modelling were available. The sites were required to have a published SEB record calculated from automatic weather station (AWS) data collected over a glacier surface during melt seasons at hourly or smaller timestep. The AWS data needed to include measurements of all four components of the radiation balance, incoming (*SWin*) and outgoing shortwave (*SWout*), incoming (*LWin*) and outgoing longwave (*LWout*), all in W m^{-2} . In addition, other SEB components needed
110 to be calculated using accepted best-practice methods (e.g. turbulent fluxes calculated using bulk aerodynamic methods) and avoiding potentially inaccurate assumptions (e.g. surface temperature fixed at $0\text{ }^{\circ}\text{C}$ regardless of SEB). Note that published values of surface melt and SEB fluxes are used in these analyses rather than being recalculated from near-surface meteorology and radiation. Thus, differences in the methods used to calculate SEB may introduce some uncertainty, but the values are congruent with previous studies, and no additional validation is needed. A call for datasets was made on *Cryolist* in January
115 2020, and data from over 30 sites was offered. After assessing each dataset against the criteria above, 16 sites were selected for analysis (Figure 1 and Table 1). These sites covered many of the mountain glacier regions including continental North America, the European Alps, Norway, Greenland, the Himalaya, tropical glaciers in Africa and the Andes, the arid region of central Chile and the Southern Alps of New Zealand. It is worth noting that no suitable datasets were made available from some large regions of mountain glaciers including Alaska, Patagonia and Asia outside of the Himalaya.

120

As most AWS sites are in ablation areas, they follow a broad pattern of decreasing altitude with distance from the equator (Figure 2). Note that two locations have observations in both the ablation and accumulation area - Conrad Glacier (CABL, CACC) and Mera Summit (MERA) / Naulek (NAUL, an ablation area of Mera Glacier). Records from the same site in different years were also joined into continuous records (CABL and NAUL). Records from CABL, CACC and NORD cover only
125 summer periods and CHHO has three two-month periods throughout the year, otherwise the records span all months of the year and range from 46 to 3231 days in length.

130 **Figure 1:** Map showing location of study sites with short names (See Table 1 for full names) along with glacier areas from the Randolph Glacier inventory (black outlines). Note the two Conrad Glacier sites (CABL, CACC) are shown as CONR and the two Mera Glacier sites (MERA, NAUL) as MERA.

135 **Figure 2:** Altitude and latitude of study sites. Open circles show the position of southern hemisphere sites against northern hemisphere sites for comparison.

140

2.2 Data processing

Data from each site were taken through several processing steps as outlined in Figure 3. After basic quality control and homogenisation (described below), a timeseries of cloudiness was generated for each site (Section 2.3), melting periods and the main melt season were defined (Section 2.4), after which cloud effects on melt were analysed (Section 2.5).

145

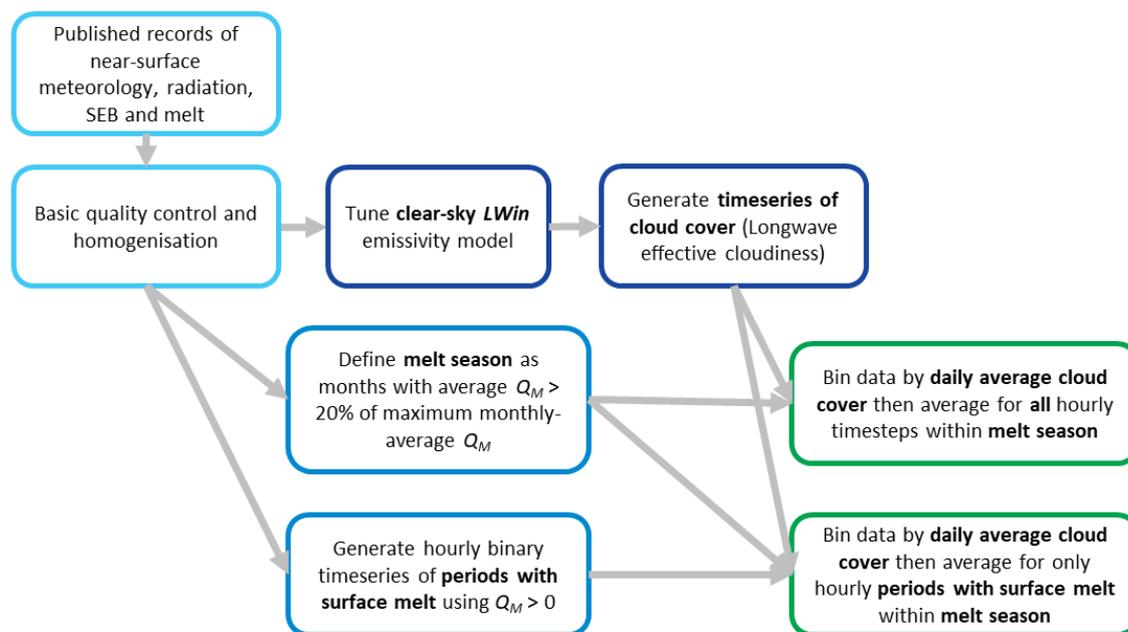

Figure 3: Step used to process and analyse data.

Basic quality control and homogenisation involved the following steps:

- 150
- Sub-hourly data resampled to hourly time steps
 - Times converted to local solar time using longitude rounded to nearest full hour offset from UTC.
 - Data cut to full days only (no days with partial missing data)
 - Naming, units and sign conventions of variables standardised
 - Periods with missing radiation data ($SWin$, $SWout$, $LWin$, $LWout$) removed

155

 - Periods with missing near-surface air-temperature (T_a ; °C) or relative humidity (RH) data removed.
 - Negative values of $SWin$ and $SWout$ set to 0
 - Values of $LWout > 315.6 \text{ W m}^{-2}$ reset to 315.6 W m^{-2}
 - Net radiation ($Rnet$) calculated from corrected values of ($SWin$, $SWout$, $LWin$, $LWout$)
 - Near-surface vapour pressure (e_a ; hPa) calculated from T_a and RH using Buck (1981)

160

 - Surface temperature (T_s ; °C) calculated from $LWout$ if not provided
 - Daily average albedo calculated as ratio of daily sums of $SWin$ and $SWout$
 - If Q_M or surface melt calculated from SEB model is not provided, then Q_M is calculated as positive values of SEB when $T_s > -0.1 \text{ °C}$

Monthly statistics (averages, frequencies by bin etc.) were only calculated when at least 10 days of data from a given month
 165 were available. Figures A1 and A2 show monthly average meteorology and SEB fluxes for each site used in the analysis.

2.3 Defining clear-sky and cloudy periods using incoming longwave radiation

For each site, timeseries of cloudiness were derived from measured $LWin$, e_a and near-surface air temperature ($T_{a,K}$; K). First, the effective sky emissivity (ε_{eff}) was calculated using:

$$170 \quad \varepsilon_{eff} = LWin / \sigma T_{a,K}^4 \quad 3$$

While $LWin$ is influenced by emission from surrounding terrain, the sky-view factor at all sites is close to 1 and horizons at all sites are below the limit of the sensor field of view, so no corrections were needed here.

175 Timeseries of theoretical clear-sky emissivity (ε_{cs}) at each site were defined using the Brutsaert (1975) curve as modified by Konzelmann (1994) with the exponent set to 1/7 after Dürr et al. (2006):

$$\varepsilon_{cs} = \varepsilon_{ad} + b(100 \times e_a / T_{a,K})^{(1/7)} \quad 4$$

180 where ε_{ad} is an elevation-dependent dry air emissivity term (varying between 0.18 and 0.23) defined here using ε_{ad} values determined from radiative transfer modelling in Dürr et al. (2006) for the European Alps that are regressed against elevation (z ; m above sea level):

$$\varepsilon_{ad} = 0.2351 - z \times 9.636 \times 10^{-6} \quad 5$$

185

For each site, Equation 4 was fitted to the lowest 10% of $LWin$ in 30 $e_a/T_{a,K}$ bins (Figure A3) by finding the value of b (in 0.001 steps) that gave the smallest root mean square error (RMSE). This step used only hours with valid $LWin$, e_a and $T_{a,K}$ values and $RH < 80\%$. Optimised values of b and RMSE are given in Table A1.

190 Timeseries of longwave equivalent cloudiness (N_ε) were then derived by fitting hourly measured ε_{eff} between theoretical clear-sky (ε_{cs}) and overcast ($\varepsilon_{ov} = 1$) emissivity values, limiting N_ε to a range 0 to 1 (Conway et al., 2015):

$$N_\varepsilon = (\varepsilon_{eff} - \varepsilon_{cs}) / (\varepsilon_{ov} - \varepsilon_{cs}); \quad 6$$
$$N_\varepsilon[N_\varepsilon > 1] = 1; N_\varepsilon[N_\varepsilon < 0] = 0$$

195

Following Giesen et al. (2008), clear-sky conditions are defined as $N_\varepsilon \leq 0.2$, partly cloudy as $0.2 > N_\varepsilon > 0.8$ and overcast as $N_\varepsilon \geq 0.8$. Daily average, rather than hourly average, N_ε was used to define cloudiness to reduce noise, limit the influence of diurnal cycles in variables and focus on synoptic scale (daily) variability in cloud – SEB relationships. Note that moderate

200 values of daily average cloudiness can indicate either patchy cloud cover and/or a mix of overcast and clear-sky conditions during a day. Cloudiness can be derived from $SWin$ (e.g. Greuell et al., 1997; Sicart et al., 2006; Mölg et al., 2009a; Kuipers Munneke et al., 2011) but was considered a less appropriate metric here as its calculation relies on setting a typical cloud extinction coefficient that differs between sites (Pellicciotti et al., 2011). In addition, shading of $SWin$ introduces further uncertainty, especially in winter and $SWin$ does not provide meaningful values during the night time.

2.4 Definition of melt season and periods with surface melt

205 For each site, a melt season was defined as the months in which monthly-average Q_M at the site was greater than 20% of the maximum monthly-average Q_M for the same site (Figure A2; A4). This proved a simple method to retain months with substantial melt but exclude winter months where melt is infrequent. The sensitivity of this choice was assessed by replicating key results using only months with monthly-average Q_M greater than 80% of the maximum monthly-average Q_M for that site. Rather than only selecting individual melt events for analysis, averages over all timesteps in the melt season were used to
210 better understand the relationships between cloudiness, surface radiation and near-surface meteorology, without skewing the data towards melt episodes that may have atypical meteorology. To identify the times surface melt occurred and to quantify the contributions of SEB components to Q_M , periods with surface melt were defined as hourly timesteps with $Q_M > 0$.

2.5 Analysis of cloud effects

215 The relationship between cloudiness, meteorology, SEB and melt is assessed by binning the timeseries of different variables by daily average cloudiness. Five evenly sized bins were used with bin centres at $N_\epsilon = 0.1, 0.3, 0.5, 0.7$ and 0.9 , with the top and bottom bins corresponding to clear-sky and overcast conditions, respectively. Data within each bin were then averaged across all days within the main melt season to demonstrate the average relationships between cloudiness and different variables.

220 In sections 3.2, 3.3 and 3.4, we use the term cloud effects to describe the change in a variable during cloudy conditions with respect to clear-sky conditions. In studies of net radiation, the cloud effect (CE) is defined as the difference between average and clear-sky conditions. Here we extend the concept to Q_M in order to describe the average change in melt related to clouds, even though clouds are not the only meteorological forcing responsible for changes in Q_M . We calculate CE for all net radiation components ($SWnet$, $LWnet$, $Rnet$) and Q_M . Here, we calculate CE by subtracting the average value in the clear-sky bin ($N_\epsilon \leq$
225 0.2) from the average value equally weighted across all cloudiness bins. Equally weighting each cloudiness bin ensures that differences in the frequency of different cloud conditions do not skew the data between sites.

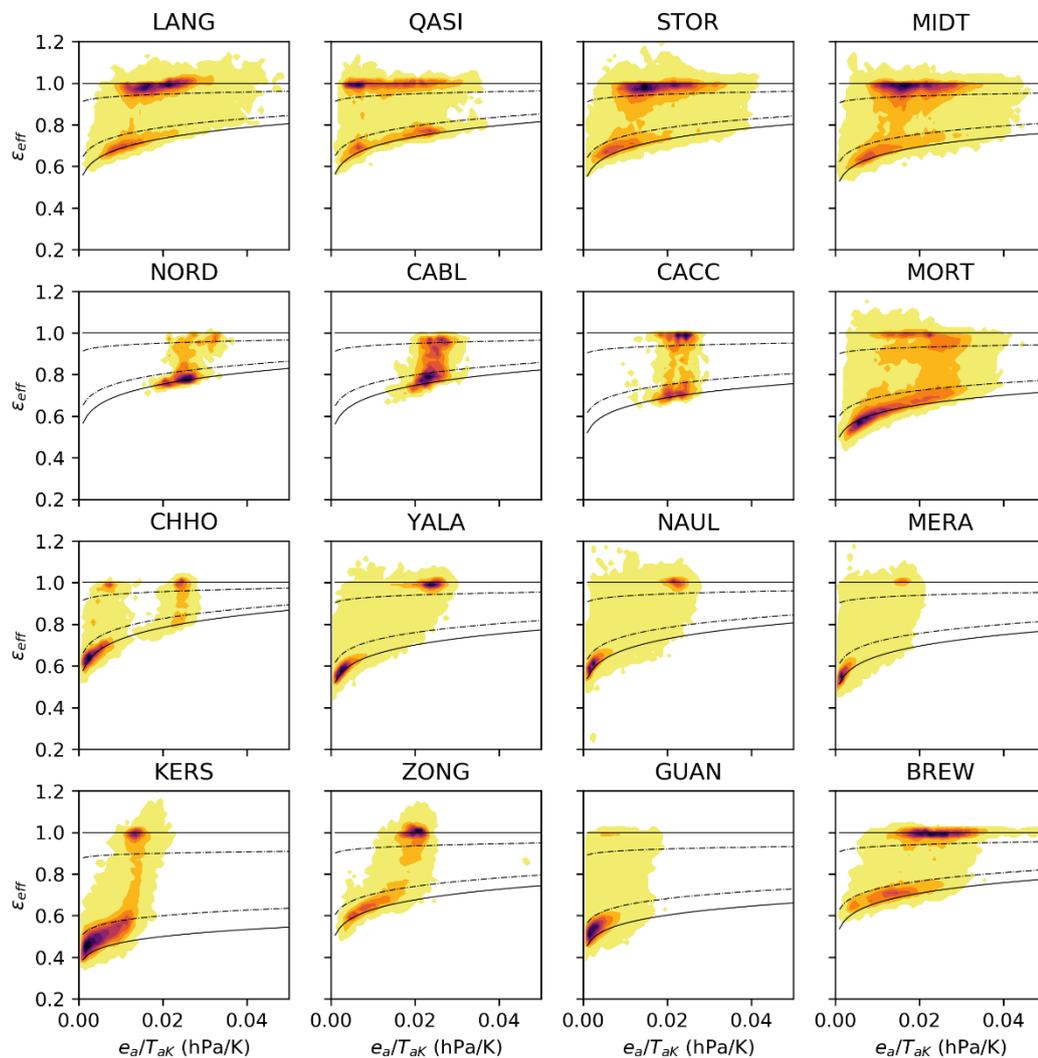

3 Results

3.1 Cloud metrics

3.1.1 Effective sky emissivity and fitted clear-sky curve

230 The derivation of clear-sky emissivity from $LWin$ highlighted substantial variations in the relationship between near-surface meteorology and $LWin$ between the sites. On an hourly basis, most sites show a preference for either clear-sky or overcast conditions, as shown by the darker colours around the clear-sky and overcast emissivity (Figure 4). Sites in the Himalaya (CHHO, YALA, NAUL, MERA) showed a distinct seasonality with predominately warm/wet/overcast or cold/dry/clear-sky conditions. Tropical and arid glacier sites (KERS, GUAN) show a much lower ϵ_{cs} for the same surface vapour pressure, in part
235 due to the high elevation (therefore low ϵ_{ad}), but also due to the low value of b (Equation 4; Table A1), which indicates a thinner atmospheric water vapour profile above the surface compared to Himalayan sites at similar altitudes. Mid-latitude sites with records covering the full annual cycle in Europe (LANG, MIDT, MORT, STOR) and New Zealand (BREW) show a similar preference for cold/dry/clear-sky or warm/wet/overcast conditions, while QASI shows a greater frequency of cloud at
240 MORT, STOR) show more frequent partial cloud than many other sites. Note that the short summertime records from Canada (NORD, CABL, CACC) and Europe (MIDT, MORT, STOR) do not capture the full spectrum of conditions at these sites.

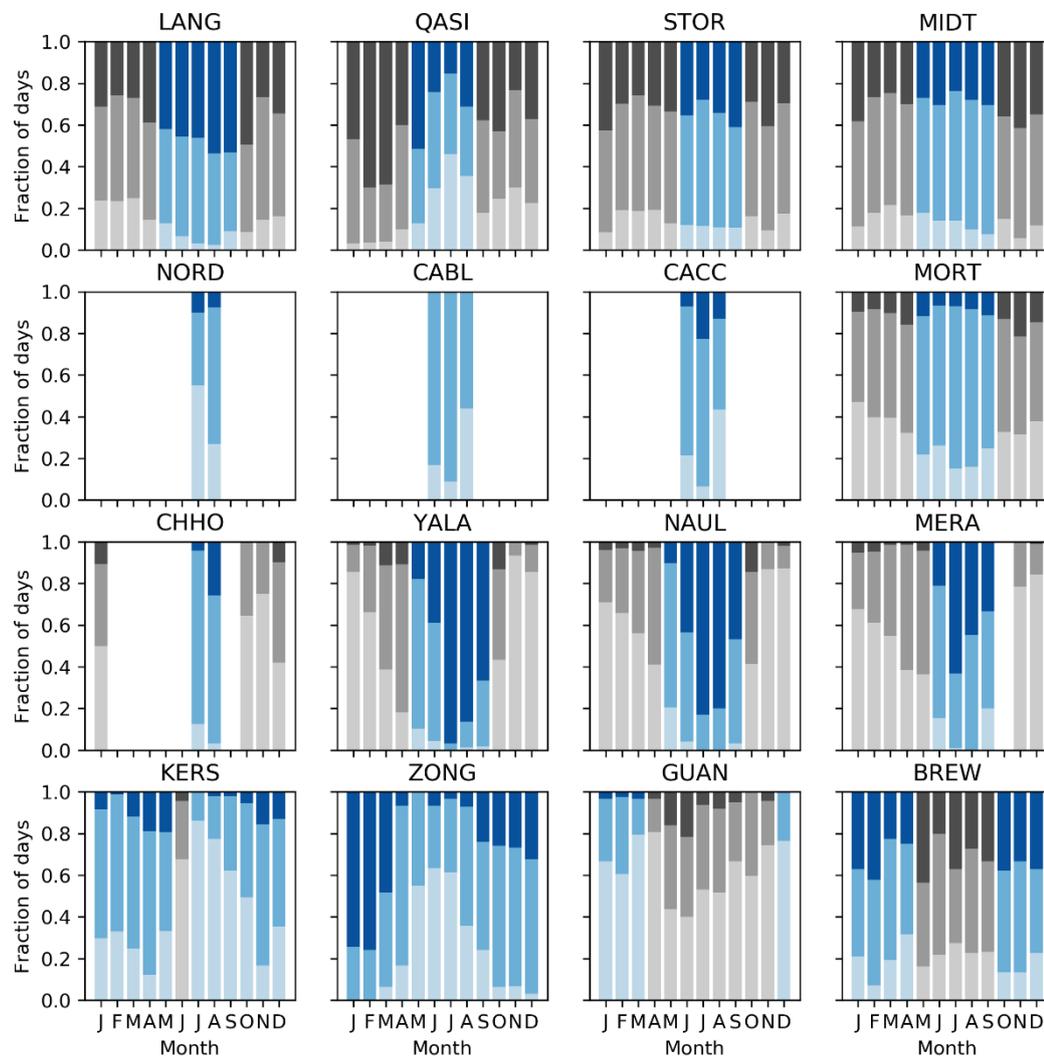

245 **Figure 4: Observed ϵ_{eff} (filled contours) versus $e_a/T_{a,K}$ for sites arranged by latitude. Also shown are calculated ϵ_{cs} (lower solid line) ϵ_{ov} (upper solid line) and ϵ_{eff} at clear-sky and overcast limits of $N_\epsilon = 0.2$ and $N_\epsilon = 0.8$, respectively (lower and upper dashed lines, respectively). Contours created from 2D histogram with common x and y bins across all sites with colours in 10 steps between 1 and the maximum number of hours in any x, y bin for each site.**

3.1.2. Monthly cloud frequency

250 The frequency of clear-sky, partial-cloud and overcast conditions also shows distinct regional and seasonal variations (Figure 5 for daily average, Figure A4 for hourly periods). Mid-latitude glaciers in maritime locations show very limited seasonality (BREW, STOR, MIDT) and a high percentage of overcast conditions, except for LANG that displays more frequent overcast conditions during the melt season and QASI that shows a tendency towards more frequent clear-sky conditions during its melt

season. Mid-latitude sites in continental locations (NORD, CABL, CACC, MORT) show less frequent overcast and more
255 frequent partial-cloud conditions than the mid-latitude maritime sites, with MORT showing more frequent partial-cloud
conditions during the melt season and more frequent clear-sky conditions in the winter. Most Himalayan sites (YALA, MERA,
NAUL) show much stronger seasonality, with more frequent overcast conditions during the melt season, except CHHO, which
shows weaker monsoon influence (fewer overcast conditions) being on the transition zone between monsoon and arid regions.
While ZONG experiences melt most of the year, melt rates are higher during the cloudier months from September through
260 April corresponding with marked seasonal changes in cloud and SEB caused by the tropical climate (Figure A2). KERS
experiences less cloud from June through October, with low melt rates year-round. GUAN experiences the least cloud, with
predominately clear-sky conditions and only sporadic melt during austral summer.

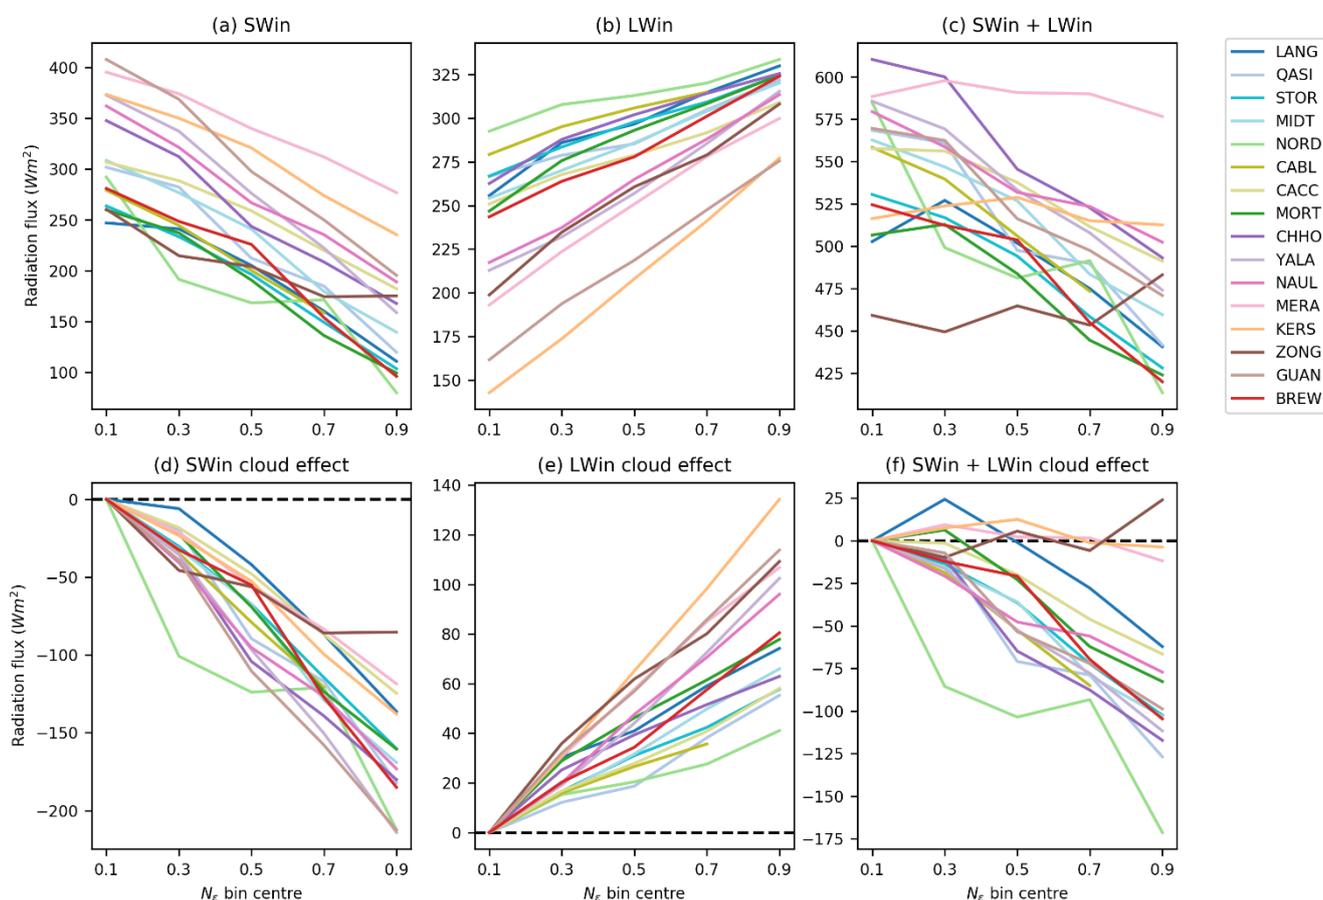

265 **Figure 5: Monthly fraction of clear-sky (light shading), partial-cloud (mid shading) and overcast conditions (dark shading) defined using daily average cloudiness (N_e). Months defined as within the ‘melt season’ are shaded blue.**

3.2 Cloud effects on melt-season surface radiation

270 An estimate of the direct effect of clouds on the SEB is gained by examining the variation of incoming radiation ($SWin$ and $LWin$) with cloudiness (Figure 6). At most sites the average direct effect of clouds on incoming radiation is negative, steadily decreasing with increasing cloud cover to between -60 and -170 W m^{-2} (Figure 6f). The exceptions are low-latitude and high-altitude sites KERS, MERA, and ZONG, where comparatively small decreases in $SWin$ with cloudiness (Figure 6d) are compensated by large increases in $LWin$ (Figure 6e). The large variation in $SWin$ and $LWin$ cloud effects between sites suggests

that different cloud types and cloud properties play a role in determining radiative forcing and this should be investigated in
 275 future work. We note that changes in the profile of water vapour and air temperature (estimated by e_a and T_a) also influence
 $LWin$ (and to a much lesser extent $SWin$). Hence, the direct cloud effects shown here represent the combined effects of direct
 radiative forcing and changes to atmospheric profiles of water vapour and temperature, in contrast to analyses of cloud radiative
 forcing that consider the changes in incoming radiation with respect to calculated clear-sky values (e.g. Sicart et al., 2016).

280

Figure 6: (a)-(c) Average melt season incoming radiation fluxes ($SWin$, $LWin$) for different daily average cloud conditions (N_e), (d)-(f) as for (a)-(c) expressed as change from clear-sky conditions ($N_e \leq 0.2$). Note y-axis range differs between panels.

By analysing the change in net radiation fluxes ($SWnet$, $LWnet$ and $Rnet$) the effect of albedo and surface temperature is
 285 included with the direct effect of clouds on incoming radiation (Figure 7). A clear increase in $Rnet$ during cloudy periods
 (positive $Rnet$ cloud effect), aka ‘radiation paradox’, is observed at some sites: ZONG, MERA, LANG (Figure 7f), due to
 small negative $SWnet$ effect and strong positive $LWnet$ effect (Figure 7d,e). GUAN and KERS have a similarly strong positive
 $LWnet$ effect at higher values of N_e , but much more negative $SWnet$ effects cancel these out. For most sites, the $Rnet$ cloud

effect is small and negative (0 to -20 W m^{-2}). Many of these sites show a decrease in R_{net} only at higher values of N_e , while
 290 3 sites show the highest R_{net} in partial-cloud conditions, emphasising that the relationship between R_{net} and cloudiness is not
 always linear. NORD, CABL, QASI, and CHHO all show a strong negative R_{net} cloud effect, driven by strong negative SW_{net}
 effect and weak LW_{net} cloud effect. For the two sites with measurements from both the accumulation and the ablation areas,
 accumulation sites exhibit much more positive response to cloud compared with their ablation area counterparts, driven by the
 change in SW_{net} cloud effect (surface albedo) rather than large change in LW_{net} cloud effect.

295

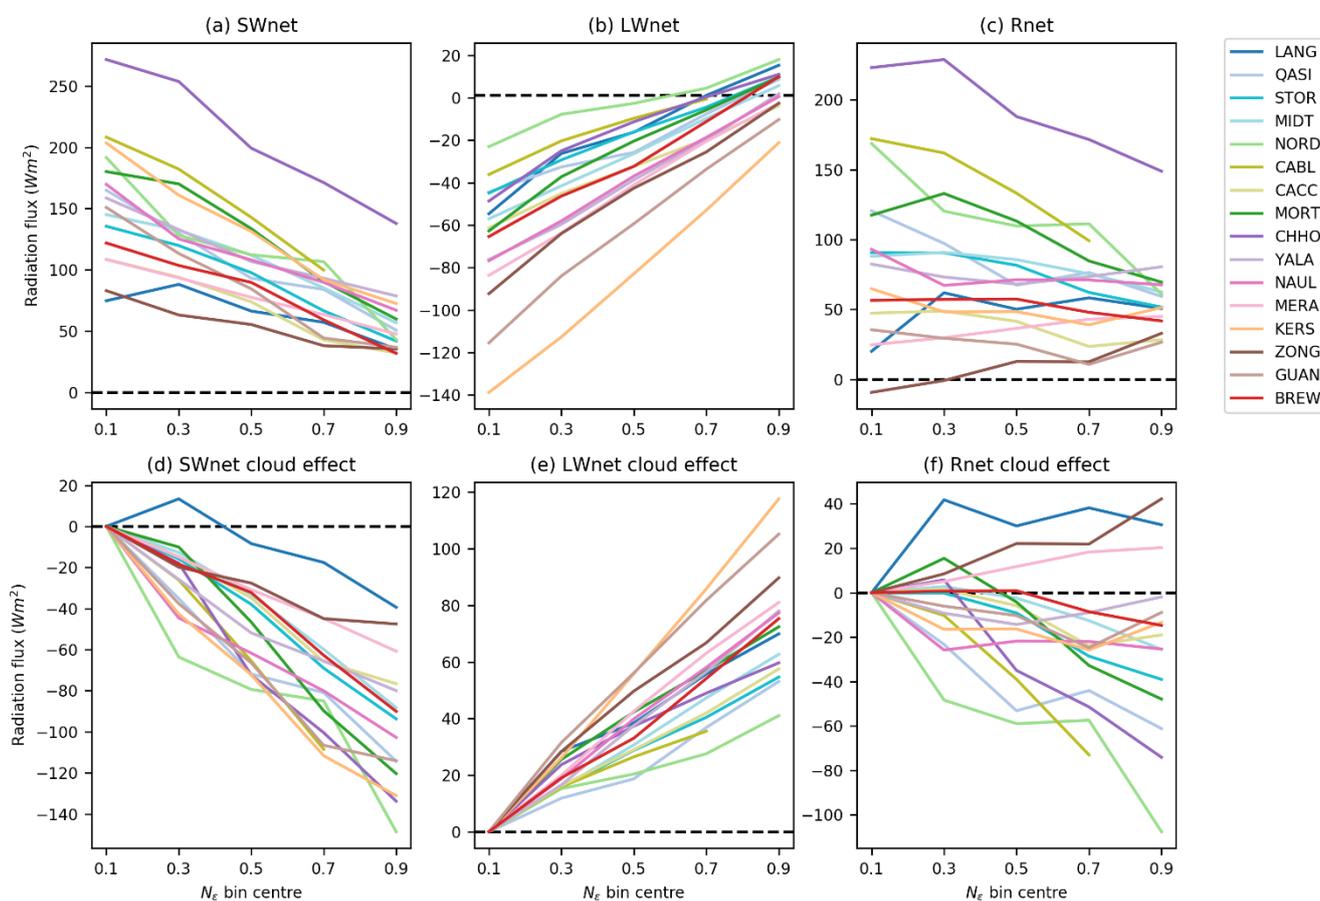

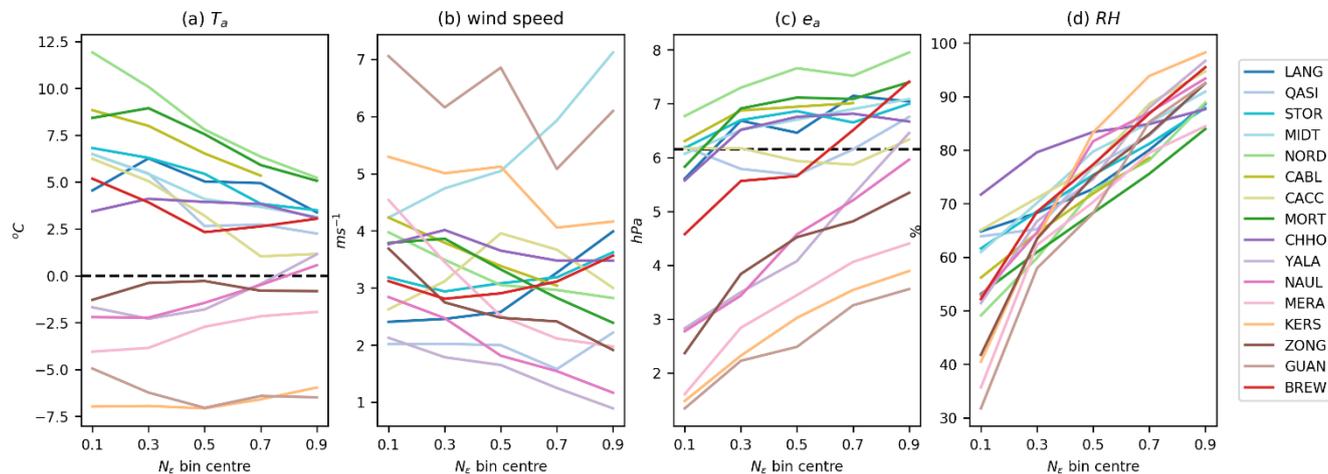

Figure 7: (a)-(c) Average melt season net radiation fluxes (SW_{net} , LW_{net} , R_{net}) for different daily average cloud conditions (N_e), (d)-(f) as for (a)-(c) expressed as change from clear-sky conditions ($N_e \leq 0.2$). Note y-axis range differs between panels.

300 3.3 Variation of near-surface meteorology with cloudiness

Alongside radiative changes, differences in near-surface meteorology are also an important driver of SEB and melt variations with cloudiness, particularly Q_s , Q_L and $LWin$. Air temperature shows a divergent relationship to cloudiness; at sites with

average melt-season $T_a \gg 0$ °C, increasing cloudiness is associated with lower temperatures, while at sites with average melt-season $T_a < 0$ °C (KERS, MERA, NAUL, YALA), cloud are generally associated with higher temperatures (Figure 8a).
 305 Average T_a varies little with cloud cover at ZONG and CHHO. At most sites, wind speed decreases with increasing cloudiness (Figure 8b). The exceptions are BREW and STOR, which show moderate increases ($< 1 \text{ m s}^{-1}$), LANG and MIDT, which show larger increases (1.6 and 2.9 m s^{-1} , respectively), and QASI and CACC, where the relationship is weak and non-linear. We note that sites where wind speed increases with cloudiness (particularly MIDT and LANG) have a wind climate that is mainly influenced by the large-scale circulation, while other sites may have a more local wind climate where local or meso-scale
 310 katabatic or convective circulations prevail (e.g. Mölg et al., 2020; Conway et al., 2021). Stronger radiative cooling during clear-sky periods may promote higher katabatic wind speeds in clear-sky conditions, though the relationship is not simple; at ZONG, strong winds during clear-sky conditions are related to large-scale forcing during the dry season (Litt et al., 2014). As expected, e_a and RH increase with cloudiness, however some sites with e_a around the saturation vapour pressure of melting surface show a weak relationship to cloudiness (e.g. QASI, CACC). The wide variation of RH in clear-sky conditions (~ 30 to
 315 $\sim 70\%$) implies that care should be taken when using RH to model cloud cover using empirical parameterisations developed for particular study areas, or even at different altitudes (e.g. NAUL vs MERA).

320 **Figure 8: Average melt season near-surface meteorology for different daily average cloud conditions (N_c). Dashed lines indicate melting point temperature in (a) and saturation vapour pressure in (c).**

3.4 Variation of melt frequency, melt amount and SEB with cloudiness

The percentage of hours with surface melt increases with cloudiness at all study sites (Figure 9). Colder sites across the Himalaya and tropical regions (except KERS) show the largest increases with respect to clear-sky conditions (up to 5 times
 325 more frequent), while BREW, MORT and LANG all show moderate increases up to 1.5 times more frequent in overcast

conditions. Other European and North American sites show comparatively high melt frequency across all cloud conditions, indicative of the warm conditions where e_a exceeds that of a melting ice/snow surface. Even in these conditions, periods with surface melt still become more common with increasing cloudiness, with 100% of overcast periods at NORD experiencing melt (Figure 9a). While analysis of diurnal patterns of melt is beyond the scope of this paper, it is likely that night time cooling during clear-sky conditions delays the onset of melt in the morning, whereas in cloudy conditions the surface can remain close to melting conditions day and night. MERA shows the largest increase in melt frequency with cloudiness, with melt 5 times more frequent in overcast (26% of overcast conditions) compared to clear-sky conditions (5%). A consistent increase with cloudiness is observed at MERA but caution is warranted given the small number of hours with melt in clear-sky conditions (20 hours).

335

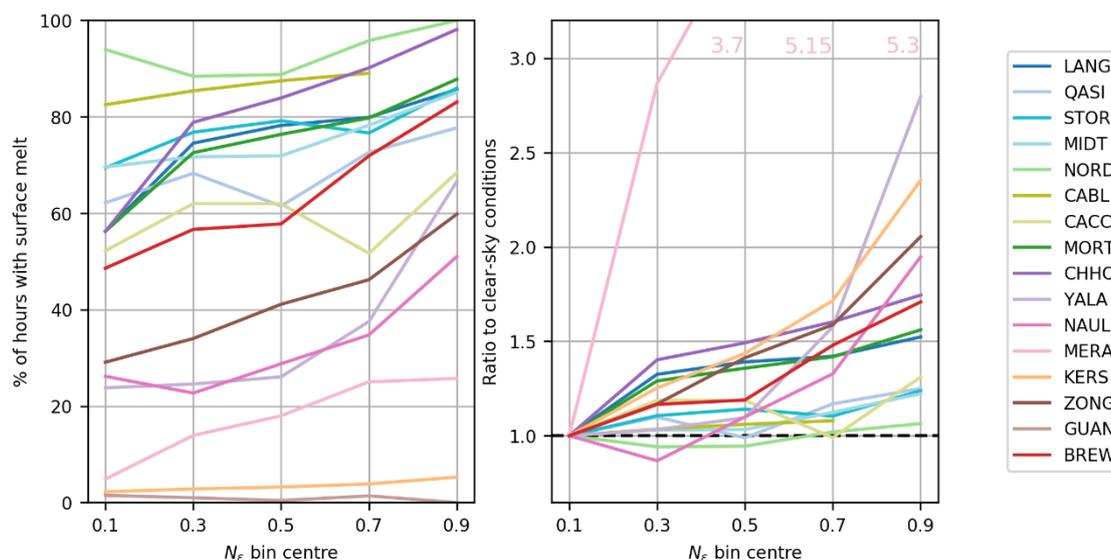

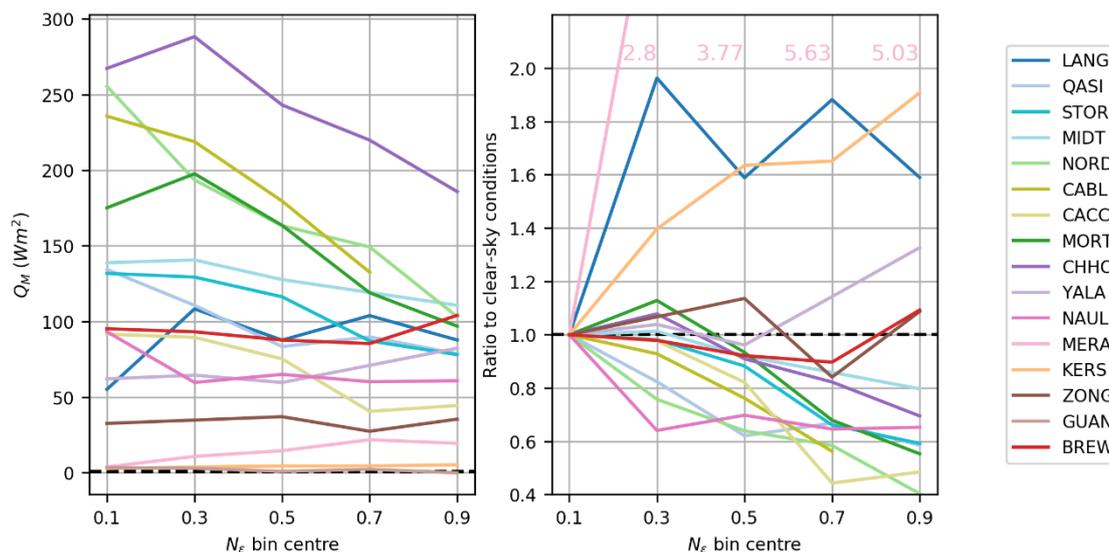

Figure 9: (a) Percentage of hours with surface melt for different cloud conditions (N_e) during melt season, (b) as for (a) shown as fraction with respect to clear-sky conditions ($N_e \leq 0.2$). Note GUAN is excluded from panel (b) due to insufficient datapoints and for clarity some points for MERA are shown as text within the panel.

340

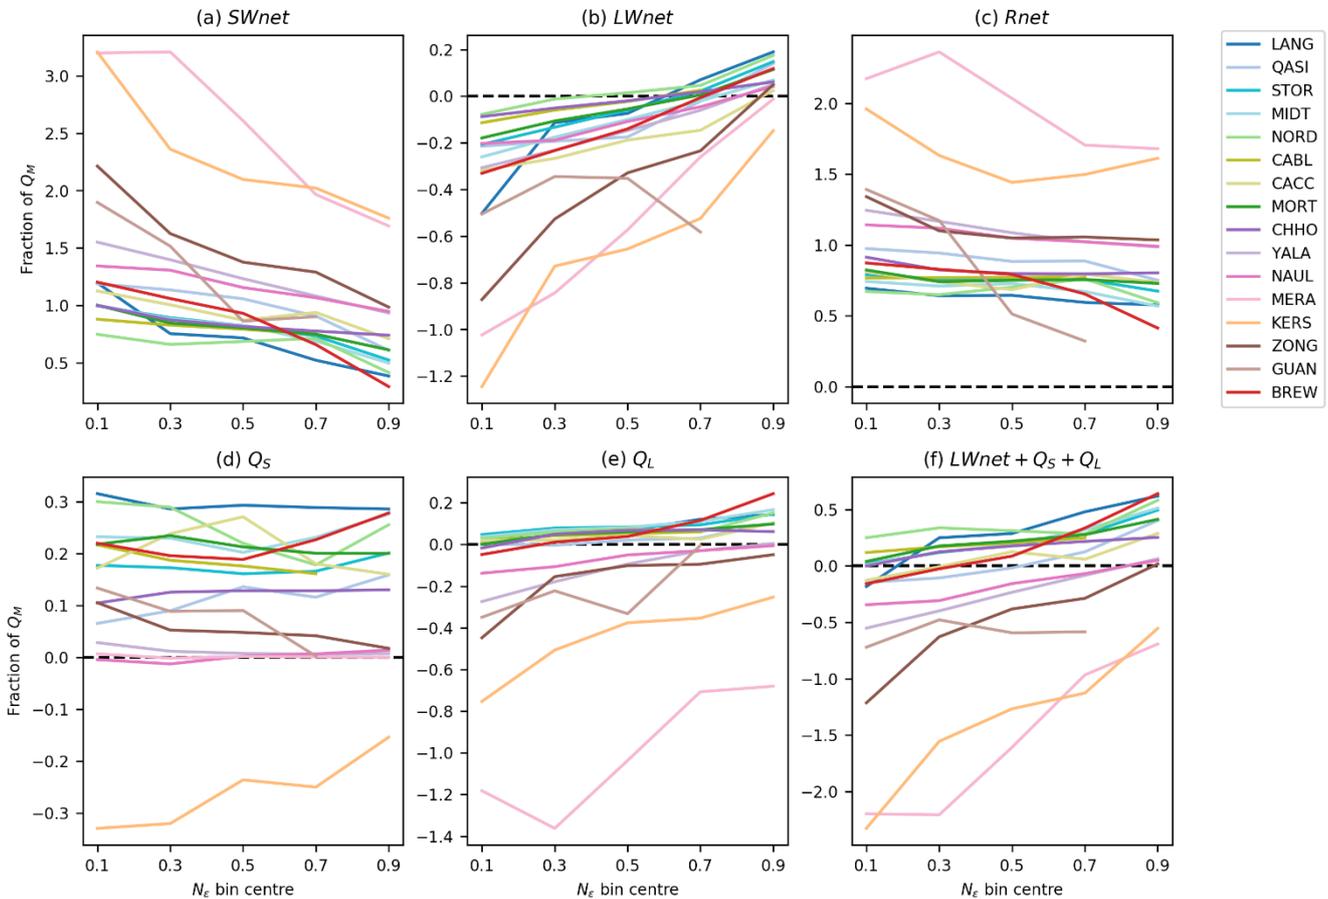

In contrast to the fraction of time with surface melt, the relationship between the amount of energy available for melt (Q_M) and cloudiness does not show a universal variation, with sites showing increased, decreased or no change with increasing cloudiness on average (Figure 10). Around half the sites show a general reduction of daily average Q_M with increasing cloudiness, particularly those in North America (CABL, CACC, NORD) and some European sites (MIDT, MORT, STOR) along with QASI and CHHO. LANG, MERA and KERS show large relative increase in Q_M with cloudiness, while BREW, ZONG and YALA show a more mixed response with a small increase in melt in overcast conditions. LANG and NAUL display a sharp change from clear-sky conditions to the first partial cloud bin ($N_e \sim 0.3$), but little change with increasing cloudiness.

345

350 **Figure 10: (a) Average melt season Q_M for different cloud conditions (N_e) (b) as for (a) shown as fraction with respect to clear-sky conditions ($N_e \leq 0.2$). Note GUAN is excluded from panel (b) due to insufficient datapoints and for clarity some points for MERA are shown as text within the panel.**

As cloudiness increases, the source of Q_M changes; at all sites, the contribution of $SWnet$ reduces and a greater proportion of Q_M comes from the temperature-dependent fluxes ($LWnet$, Q_S and Q_L) (Figure 11a,f; see Figure A5 for absolute values). At
 355 colder and drier sites (KERS, MERA, GUAN, NAUL, YALA, ZONG), negative Q_L reduces Q_M during clear-sky periods, but this effect reduces towards 0 as cloudiness increases. At the coldest sites (KERS, MERA and ZONG), Q_L remains negative during melt (indicating evaporation) even in overcast conditions. Small Q_S fluxes at MERA, NAUL, YALA, ZONG are due to T_a values during melt remaining around 0 °C. At other sites, the proportion of melt from Q_S remains fairly static with cloudiness, despite decreasing in absolute magnitude (Figure A5) due to decreases in T_a (Figure 8a). The exceptions are BREW,
 360 MIDT, and QASI where the contribution from Q_S increases with cloudiness and ZONG where the contribution of Q_S decreases. Note that as Figure 11 presents averages for only periods with surface melt, $LWout$ is constant and changes in $LWnet$ are entirely due to $LWin$.

365

Figure 11: Average melt season SEB terms during hours with surface melt for different cloud conditions (N_c). Variables are shown as a fraction of average Q_M during hours with surface melt in each respective cloud condition (N_c). Note y-axis range differs between panels.

4 Discussion

370 4.1 Regional and elevational patterns

Two groups of sites with a broadly similar response emerge from the above analyses, largely split by latitude, but also air temperature and continentality. The first group (YALA, NAUL, MERA, KERS, ZONG) consists of high-altitude sites in the Himalaya (excluding CHHO) and tropical regions. These sites are comparatively cold, with negative Q_L and small Q_S during melt. During cloudy conditions, these sites experience warmer and calmer conditions, reduced evaporation/sublimation (less negative or, at times, positive Q_L) and a large increase in the fraction of time that melt occurs, regardless of the seasonality of cloud or the typical cloud conditions (e.g. KERS vs MERA). These sites also generally experience greater Q_M in cloudy periods (except for NAUL) when averaged over a long melt season that includes months with marginal melt conditions. Some sites

375

experience a radiation paradox where R_{net} increases with cloudiness, while others show a small decrease in R_{net} with cloudiness. While GUAN experiences similar patterns of near-surface meteorology and radiation as the sites in this group, it experiences very infrequent melt.

The second group consists of the mid-latitude sites outside the Himalaya (LANG, QASI, STOR, MIDT, NORD, CABL, CACC, MORT, BREW) as well as CHHO. These sites experience higher average melt season T_a , and T_a generally decreases with cloudiness. Despite decreased T_a , melt becomes more frequency in cloudy conditions. With a few exceptions (e.g. BREW, LANG), Q_M decreases with increased cloudiness, though the magnitude of decrease varies widely (from 20% to 60% less in overcast compared to clear-sky conditions). CHHO stands out from the other Himalayan sites in that it has a higher average T_a that does not vary greatly with cloudiness. Here also, low albedo drives a strong negative R_{net} cloud effect that, in turn, drives a large decrease in Q_M during cloudy periods. At all sites, Q_S is positive in all cloud conditions, though the absolute magnitude is generally reduced in cloudy periods due to decreased T_a . Cloud is associated with increased wind speed at most maritime sites (LANG, MIDT, STOR, BREW) but does not show a consistent relationship to Q_M ; MIDT and STOR experience less Q_M in cloud conditions, whereas LANG and BREW experience greater Q_M due to increased wind speed and comparatively modest decreases in T_a that drive increased LW_{net} and Q_L . In the case of LANG, increased Q_M during cloud is also due to a positive R_{net} cloud effect.

Locations with AWS at two elevations highlight more positive R_{net} cloud effects at accumulation sites than ablation sites due to the higher albedo and larger difference between clear-sky and overcast emissivity. Differences in melt are stronger at the Himalayan pair, where melt is decreased in cloudy conditions at the lower sites and increased during cloud at the upper site. At the pair in Canada, both sites experience reduced melt during cloudy conditions, though in absolute terms, the decrease is larger in the ablation area.

4.2 Melt cloud effect

While the average change in Q_M with cloudiness is small at some sites, it is instructive to assess whether the average Q_M cloud effect (CE) at the various sites can be related to geographic or climatic parameters. Figure 12a,b shows the average relationship between cloudiness and melt at the various sites does not follow easy relationships with latitude or altitude. Neither average near-surface air temperature or humidity shows a clear relationship with the Q_M CE, though colder sites generally have smaller Q_M CE than warmer sites (Figure 12c, d). Changes in SW_{in} CE alone do not show a clear explanation, though when combined with influence of LW_{in} CE, a clearer pattern emerges (Figure 12f). Surface albedo shows a clear though weak correlation to Q_M CE, while the R_{net} CE shows the clearest relationship to Q_M CE (Figure 12g). In general, sites that experience a radiation paradox (LANG, ZONG, MERA) also experience greater melt in cloudy conditions (positive Q_M CE), while sites with negative R_{net} CE experience less melt in cloudy conditions (Figure 12g).

410

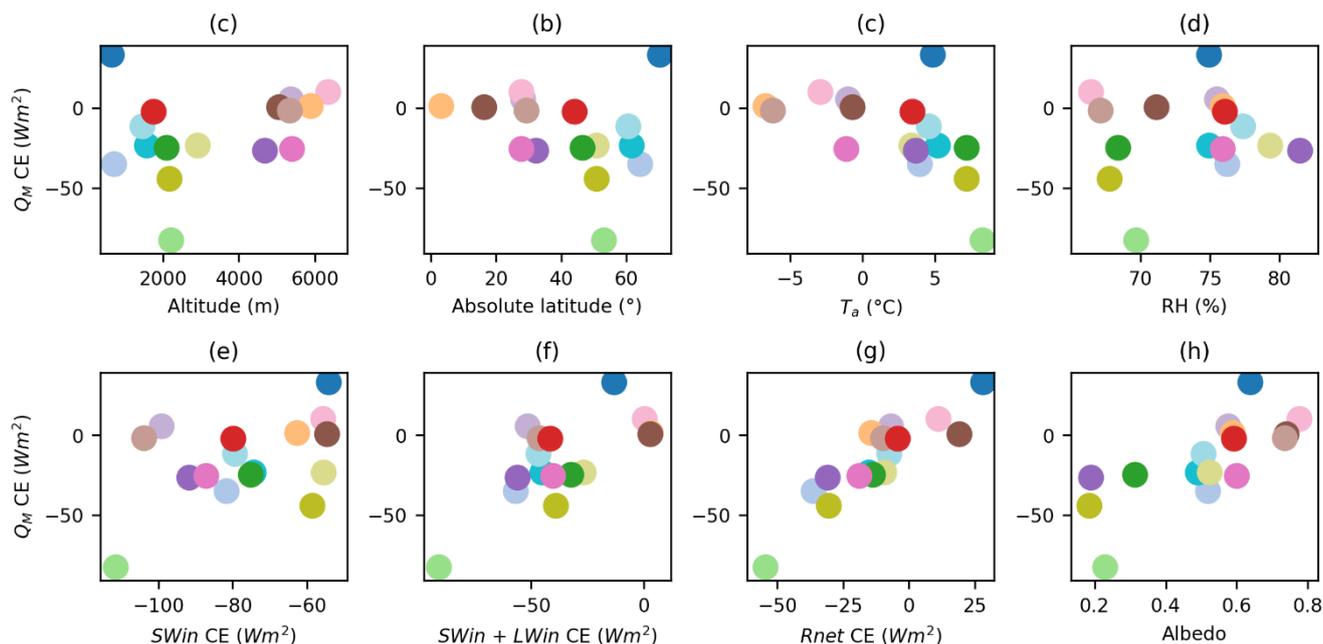

Figure 12: The variation of average melt season Q_M cloud effect (CE) with (a) station altitude, (b) absolute station latitude, (c) average melt-season T_a , (d) average melt season RH , (e) $SWin$ CE, (f) $SWin+LWin$ CE, (g) $Rnet$ CE and (h) albedo. See Section 2.5 for definition of CE. Colours denote sites – see legend on Figure 11.

415

4.3 Limitations

While efforts have been made to homogenise the datasets, it is possible that biases still affect the results. Interannual variability causes uncertainty, particularly for sites with only one or two seasons (e.g. NORD, ZONG). Giesen et al. (2008 Table 4) show that at MIDT, the contribution of SEB components to melt during clear-sky periods can vary up to 12% between years, while
 420 variability in overcast periods is less. The interannual variability is partly influenced by the seasonality of anomalies in cloudiness, with strong anomalies in spring causing the importance of Q_S to melt to change markedly. Some sites also have discontinuous records (CABL, CACC, NORD, CHHO) that do not include periods with lower melt rate outside the peak melt season. Increased clear-sky solar radiation and T_a as well as decreased albedo during the peak melt season are likely to cause
 425 $Rnet$ and Q_M cloud effects to be larger at these sites compared to those with longer records that include periods of more marginal melt. This effect is demonstrated by repeating the analysis but restricting the melt season to months with at least 80% of the maximum monthly-average Q_M , 2-3 months at each site (Figure A6). Figure 13 shows the relationship between average Q_M and N_e for the period with peak melt rates at each site. The previously large increase in Q_M with cloud at MERA and LANG becomes more variable, and Q_M is smaller in overcast conditions compared to clear-sky. This is primarily due to the removal of months with a high albedo snow surface in the early season where a strong radiation paradox drives an increase in melt
 430 during cloud periods. In clear-sky conditions, higher T_a and e_a in the peak melt season creates generally positive Q_L at these

435 sites (not shown). BREW also now shows a moderate decrease in Q_M with cloud, while ZONG shows a much stronger decrease due to marked seasonal changes in the SEB terms driving melt (less negative LW_{net} and Q_L in austral spring and summer; Figure A2). Only one site (YALA) still shows its highest Q_M in overcast conditions, but the increase is small compared to the average for the longer melt season. In fact, at outer-tropical sites such as ZONG where melt can occur in most months alongside
435 large seasonal variations in climate, the analysis here likely mixes cloud effects with seasonal changes of other meteorological forcings (such as potential solar irradiance and air temperature).

440 Seasonal changes in cloud effects on melt have been previously reported by some studies; Giesen et al. (2008) show that negative Q_M cloud effects at MIDT were restricted to July and August, with other months showing neutral or positive cloud effects; Conway and Cullen (2016) show only one month with negative Q_M cloud effect at BREW, with positive effects in other months; Chen et al. (2021) report strong negative Q_M cloud effects in July and August, with weaker negative effects in May and June, and neutral effects in September. The fact that average results are sensitive to the definition of the melt season
445 highlights the complex physical relationships between cloudiness, near-surface meteorology and melt. While future work could analyse seasonal changes in cloud effect in more detail, caution is warranted in efforts to simplify or generalise these relationships. The analysis does highlight the need to capture AWS records through the full annual cycle at study sites in order to fully understand the relationships between meteorological forcing and melt. Future work should also assess the mechanisms driving the observed covariance between cloudiness and near-surface meteorology, e.g. Do large-scale changes in airmass or local/meso-scale processes drive changes in T_a with cloud? How well are these processes represented in the datasets used to force glacier melt models on regional scales?

450

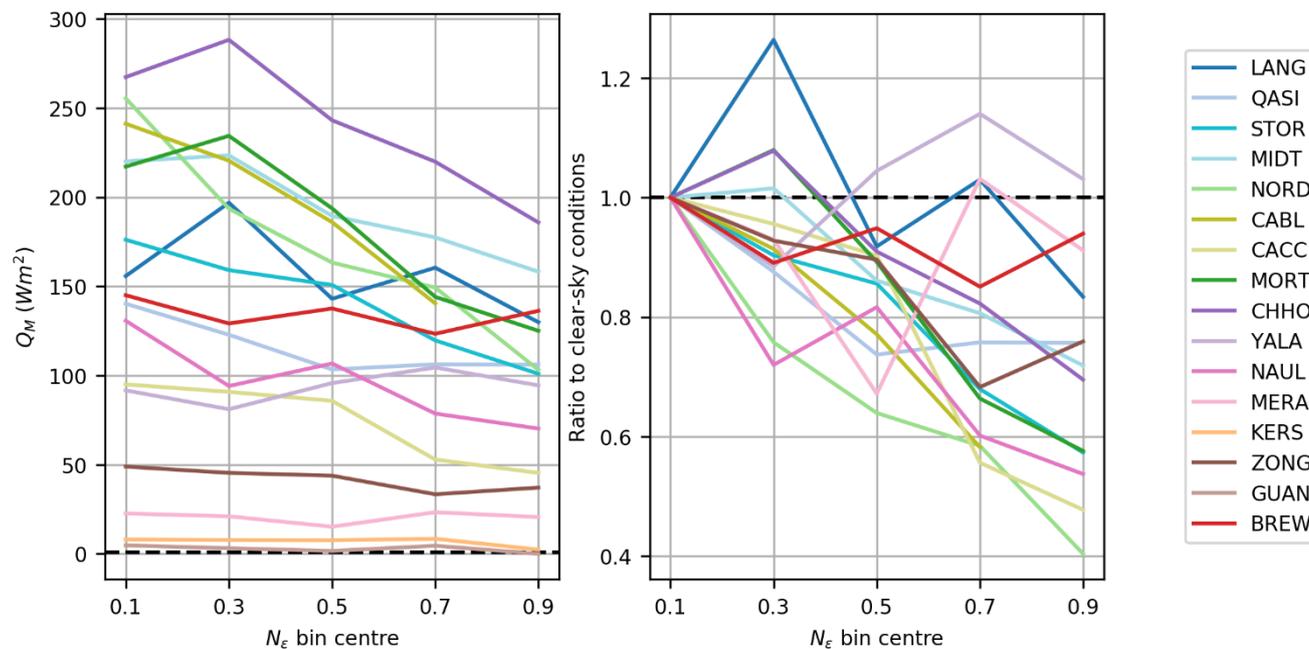

Figure 13: As for Figure 10 but only for months with > 80% of maximum monthly-average Q_M . Note GUAN and KERS are excluded from panel (b) due to insufficient datapoints.

455 The derivation of cloudiness from $LWin$ also poses challenges. At some sites (e.g. LANG, and MORT), ε_{cs} shows a poor fit at higher vapour pressure, with incoming $LWin$ during clear-sky periods being higher than that expected from the theoretical curves (Figure 4). This mismatch between theoretical and observed ε_{cs} during periods of higher e_a may cause some clear-sky periods to be misclassified as being in first partial cloud bin ($N_e \sim 0.3$). Indeed, at both LANG and MORT, the $N_e \sim 0.3$ bin shows higher melt, indicating this may be the case. The reasons for this mismatch have not been investigated, but it may be
 460 due to a different method use to correct $LWin$ data (Giesen et al, 2014) or changes in water vapour profiles in the atmospheric boundary layer.

4.4 Implications for glacier melt modelling

Previous research that identified a higher sensitivity to warming associated with cloud at BREW (Conway and Cullen, 2016),
 465 showed this occurred without increased melt during cloud periods. The effect was primarily due to increased melt frequency and temperature-dependent fluxes during cloudy periods as well as accumulation-albedo feedbacks. All sites analysed here show increased melt frequency and temperature-dependent fluxes during cloudy periods, suggesting more sites may also experience a higher sensitivity to warming associated with cloud. While a formal analysis is beyond the scope of this paper, we may therefore expect that the response of melt to past and future temperature change will be modified by changes to

470 atmospheric moisture in the form of clouds and vapour fluxes. The simplified models that are generally used to predict future
glacier change do not account for these effects. If they do include the effects of clouds, they generally only include the opposite
effect – a reduction in solar radiation by clouds – and therefore may underestimate future melt at sites where cloud cover is
not universally associated with reduced melt (e.g. high altitude and maritime glacier sites). Furthermore, any increase in clouds
and atmospheric moisture accompanying future warming may result in greater melting than predicted. Given the positive effect
475 of clouds on net radiation at snow covered and high-altitude sites, future increases in cloud cover may promote further melt,
especially during marginal melt seasons. However, caution is warranted in making generalisations as the analysis here shows
that even in this set of 16 glaciers, we find variability in the links between clouds and melt, and it seems that some processes
are site specific even in this small sample.

480 The non-linear relationships between clouds and melt motivates the use of SEB models in regional and global assessments of
glacier response to climate change. To aid in the development of globally and regionally applicable SEB models and parameter
sets, the research community should investigate creating a central open-source repository for glacier AWS and SEB datasets
along with supporting meta data. Such a repository would facilitate the easy transfer of data between researchers, streamline
processing by establishing data format and meta data standards, as well as motivating best-practice in data collection and
485 quality control. Alongside this, careful assessments of *SWin* and *LWin* and their relationship to near-surface meteorology from
global, regional and meso-scale meteorological models should be undertaken to ensure uncertainties in model input data are
reduced and to assess the need for downscaling to account for local-scale processes. As many models rely on empirical
relationships between *SWin* and *LWin* to account for local-scale changes in topography, globally applicable parameterisations
of *SWin* and *LWin* should be tested.

490 **Conclusions**

Sixteen high-quality published datasets of near-surface meteorology, radiation, and surface energy balance from very different
climate settings have been homogenised and analysed in a common framework. The analyses sought to assess how the
relationships between clouds, near-surface meteorology and surface energy balance vary in different mountain glacier
environments. Distinct regional differences in the seasonality of cloudiness are demonstrated between different mountain
495 glacier environments. On average, over the main period of melt at each site:

- Near-surface humidity is shown to universally increase in cloudy conditions, whereas a divergent relationship is found
between near-surface air temperature and cloudiness; at colder sites (average near-surface air temperature in melt
season < 0 °C), air temperature is increased in cloudy conditions, while for warmer sites (average near-surface air
temperature in melt season $\gg 0$ °C), air temperature decreases in cloudy conditions. Wind speed shows a mixed
500 association to cloudiness at different sites.

- Most sites show, on average, a modest to strong decrease in net radiation during cloudy conditions during the melt season. A few sites show a clear increase in net radiation with cloud – aka ‘radiation paradox’ – but this result is sensitive to the months used in the analysis due to seasonal changes in incoming radiation fluxes and albedo.
- At all sites, surface melt is more frequent in cloudy conditions compared to clear skies.
- 505 - At all sites, temperature-dependent fluxes contribute a larger fraction of melt energy during cloudy conditions, primarily due to increases in incoming longwave radiation and turbulent latent heat fluxes. The contribution of turbulent sensible heat generally varies little with cloudiness.
- Cloud cover does not affect daily total melt in a universal way, with some sites showing increased melt energy in cloudy conditions and other decreased melt energy. The association of clouds with melt energy is complex and not
510 amenable to simple relationships due to many interacting physical processes (varies with latitude, average melt-season air temperature, degree of continentality, season, and elevation). However, the association of clouds and melt is most closely related to net radiation cloud effect, with sites displaying a radiation paradox also showing an increase in energy for melt in cloudy conditions.
- 515 The non-linear relationships between clouds, near-surface meteorology and melt motivate the use of physics-based surface energy balance models for understanding future glacier response to climate change, particularly in areas where atmospheric moisture plays a key role both in accumulation and ablation processes (e.g. Himalaya, tropical glaciers, maritime glaciers). Future work should also look to carefully assess shortwave and longwave radiation fluxes and their relationships with near-surface meteorology in global, regional and meso-scale meteorological model analyses if we are to confidently use these tools
520 to better understand how future glacier melt will respond to changes in atmospheric temperature.

Data availability

AWS data is available from individual paper authors listed in Table 1.

525 **Author contributions**

JC conceptualized the study, curated the data, conducted the formal analyses, and wrote the manuscript. Other co-authors supplied data suitable for curation, aided in the investigation and reviewed/edited the manuscript.

Acknowledgements

JCs contribution to this research was supported by the Royal Society of New Zealand Marsden Fund. The authors wish to
530 thank the following additional people and organisations for data contributions and funding data collection and processing: Maxime Litt, Hans Oerlemans, GLACIOCLIM, PROMICE, the Greenland Ecosystem Monitoring Programme, ICIMOD,

Antoine Rabatel (IGE), Alvaro Soruco (UMSA, Bolivia), LMI GREATICE, NSERC Discovery Grant and Research Tools and Instruments, Canada Foundation for Innovation. MFA acknowledges research grants from IFCPAR and IRD, France.

655 **Appendix:**

Table A1: Optimised clear-sky emissivity coefficients and error in ε_{cs} .

Site	Fitted value of b	Root-mean squares error of calculated ε_{cs} vs ε_{eff} in selected clear-sky conditions
BREW	0.443	0.0190
CHHO	0.538	0.0280
CABL	0.483	0.0199
CACC	0.436	0.0190
GUAN	0.379	0.0292
KERS	0.291	0.0236
LANG	0.458	0.0201
MERA	0.472	0.0391
MIDT	0.428	0.0166
MORT	0.398	0.0240
NAUL	0.495	0.0378
NORD	0.489	0.0202
QASI	0.466	0.0124
STOR	0.463	0.0171
YALA	0.468	0.0240
ZONG	0.443	0.0251

660 **Figure A1: Monthly average near-surface meteorological conditions at each site. Note monthly value only shown for a site if > 10 complete days in month across full record.**

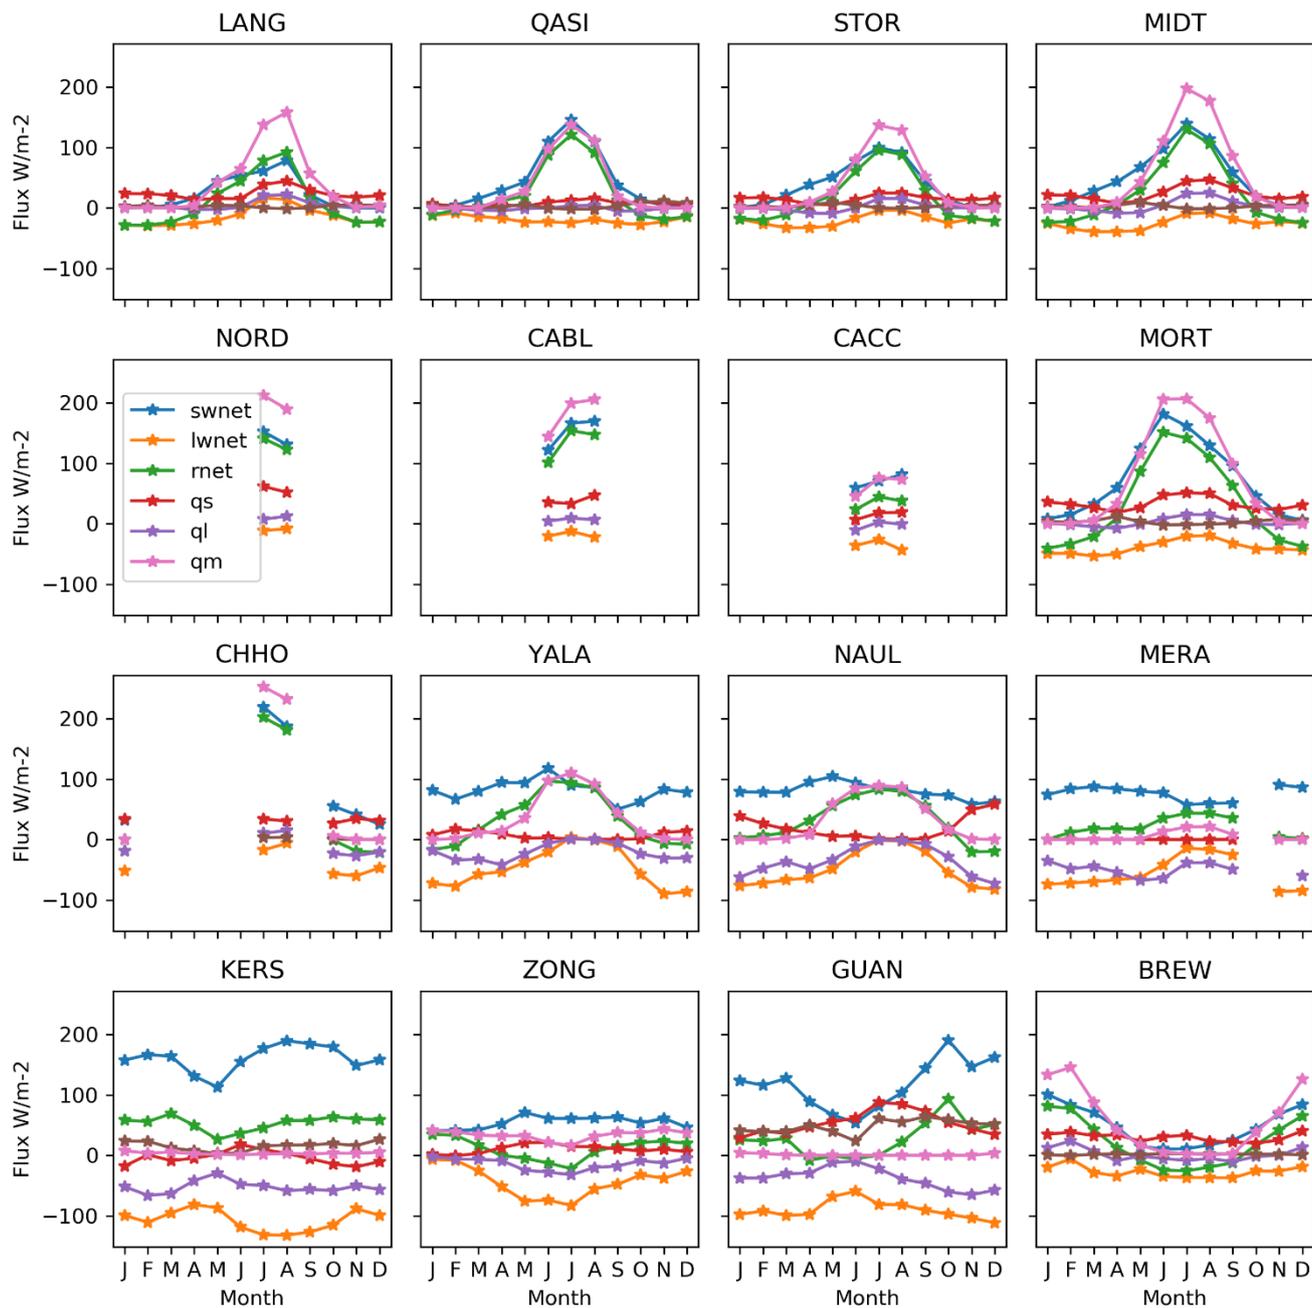

Figure A2: Monthly average SEB fluxes at each site. Note monthly value only shown for a site if > 10 complete days in month across full record.

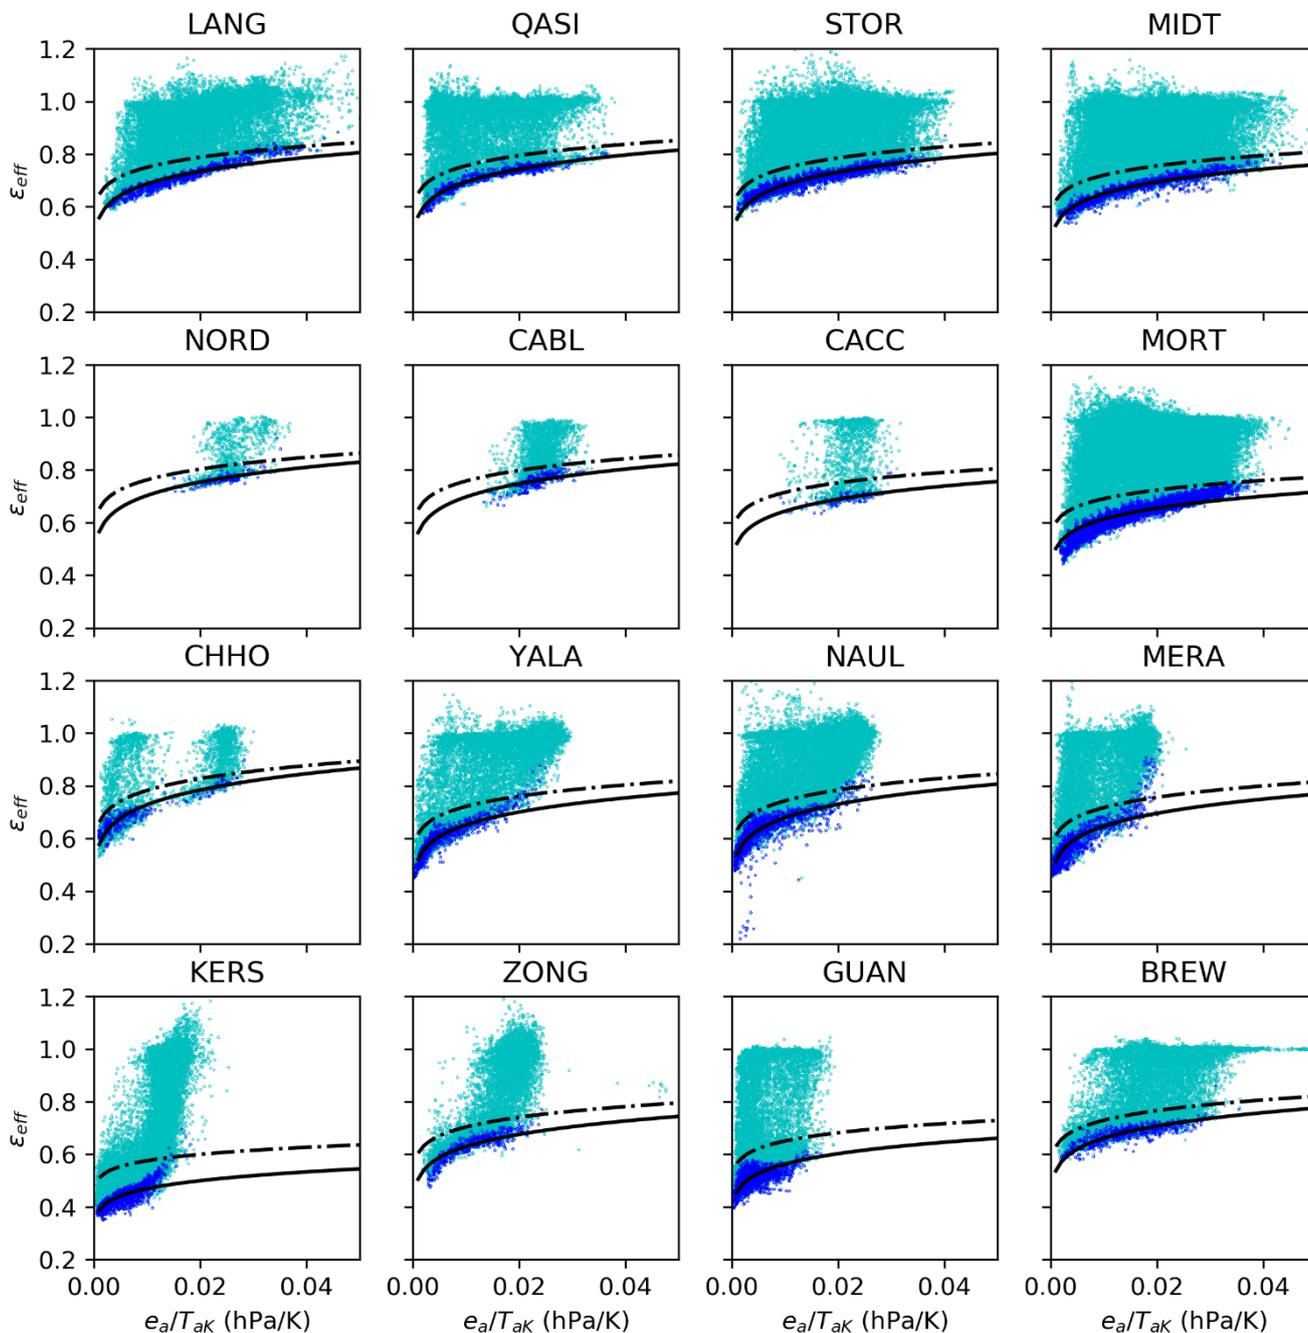

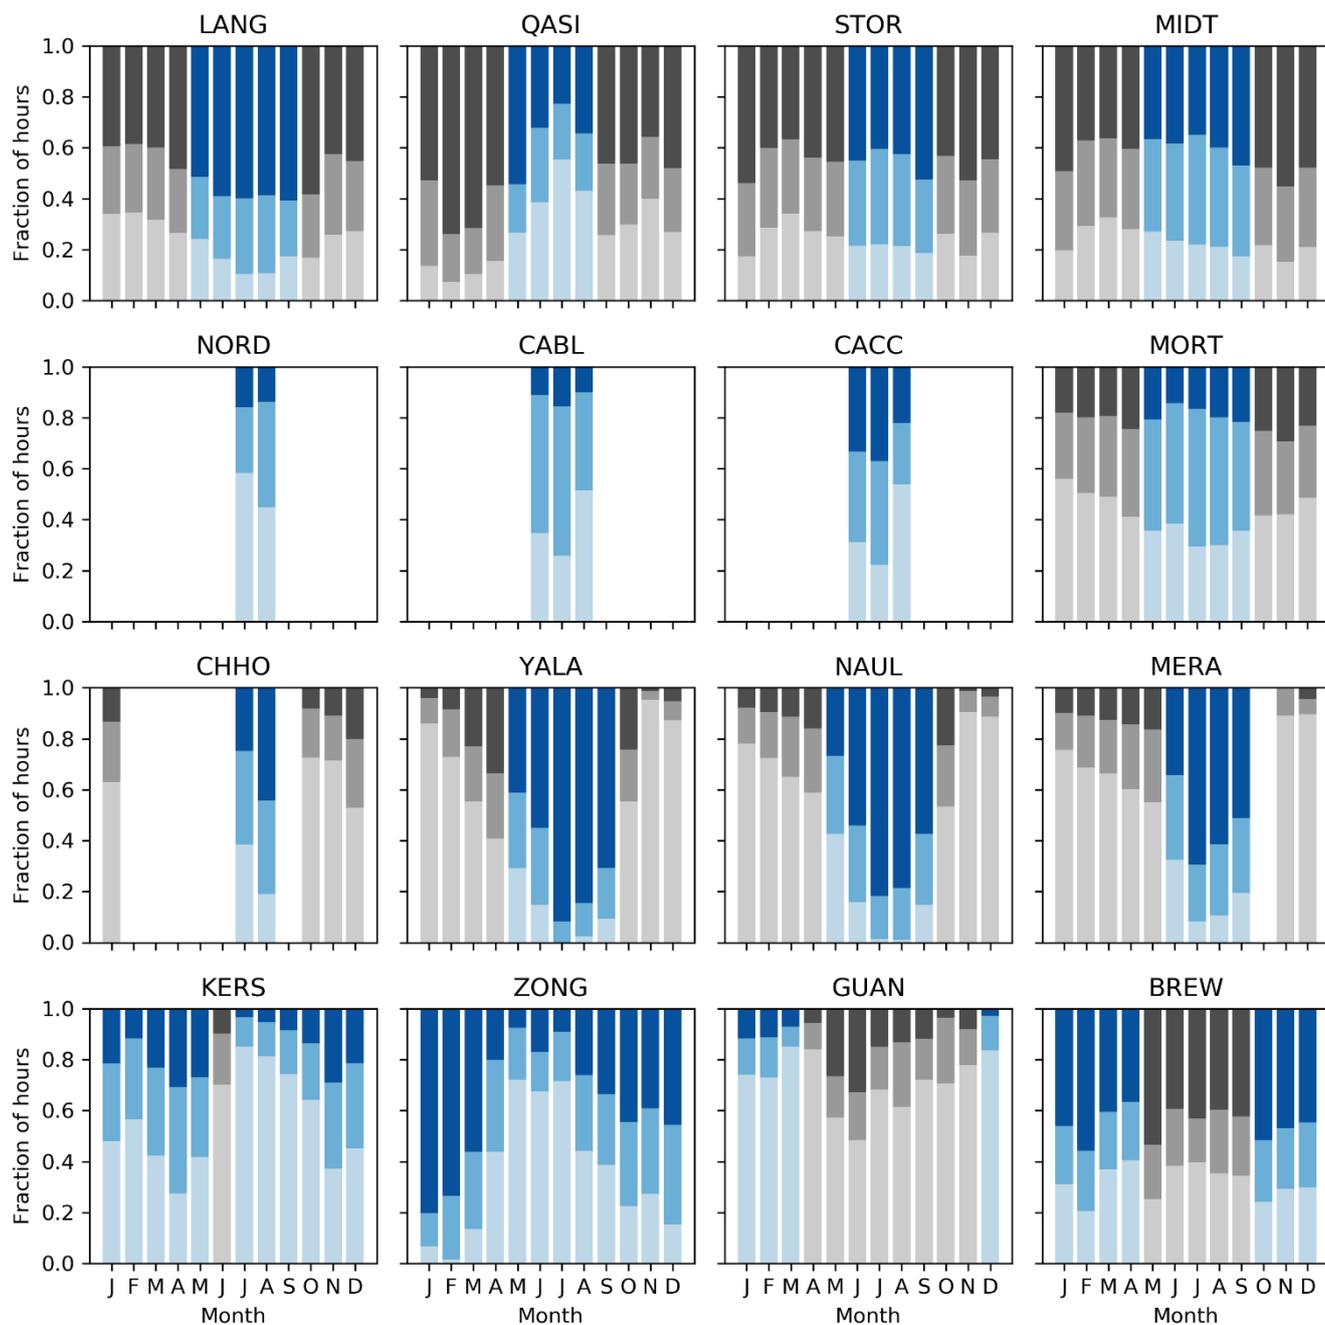

Figure A3: Observed ϵ_{eff} (points) and calculated ϵ_{cs} (solid line) fitted to lowest 10% of $LWin$ in 30 e_a/T_{aK} bins (shown in blue). Calculated ϵ_{eff} at clear-sky limit of $N_\epsilon = 0.2$ (dash-dotted line).

670

Figure A4: Monthly fraction of clear-sky, partial-cloud and overcast conditions defined using hourly cloudiness (N_e).

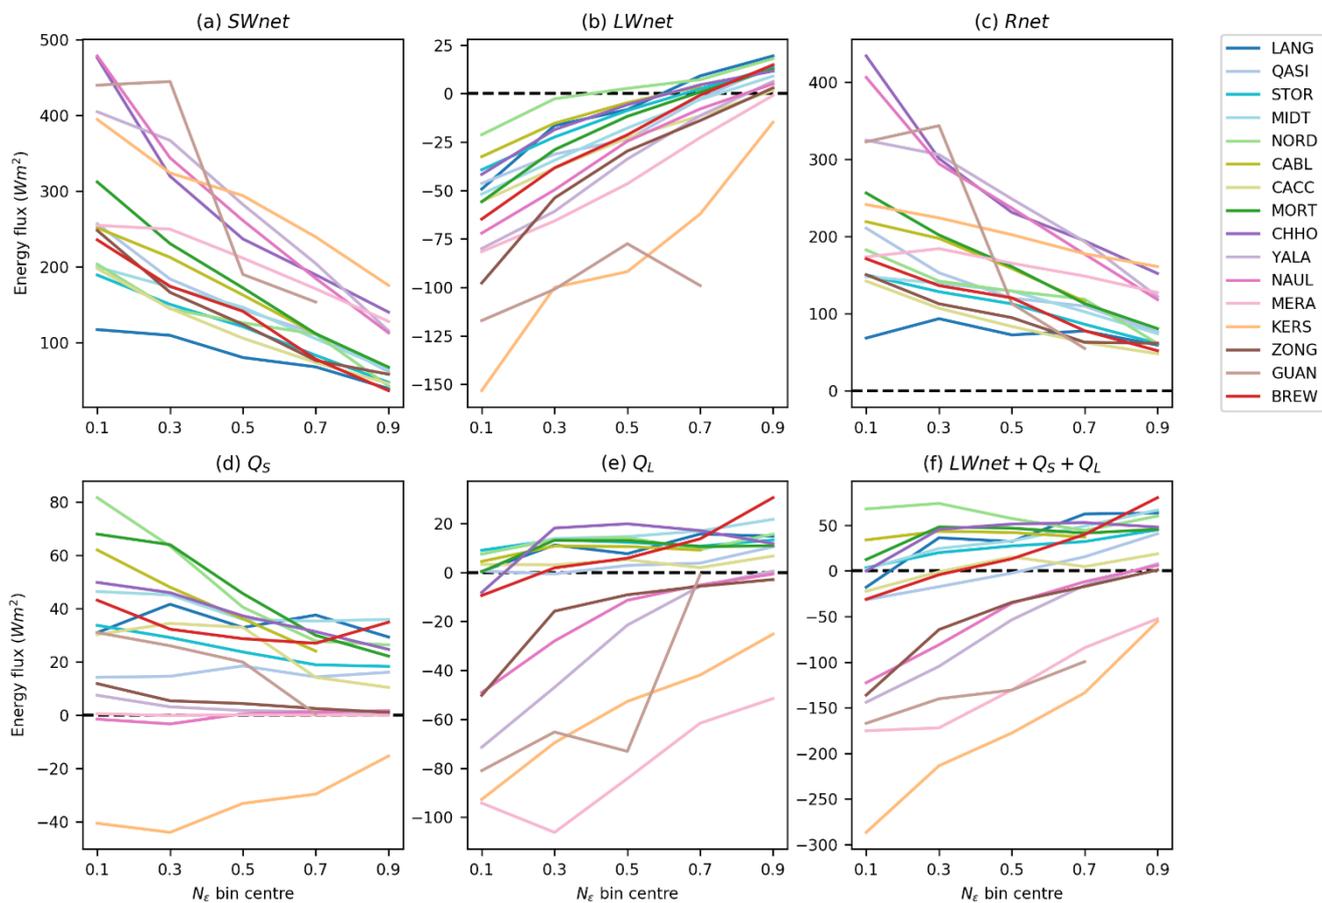

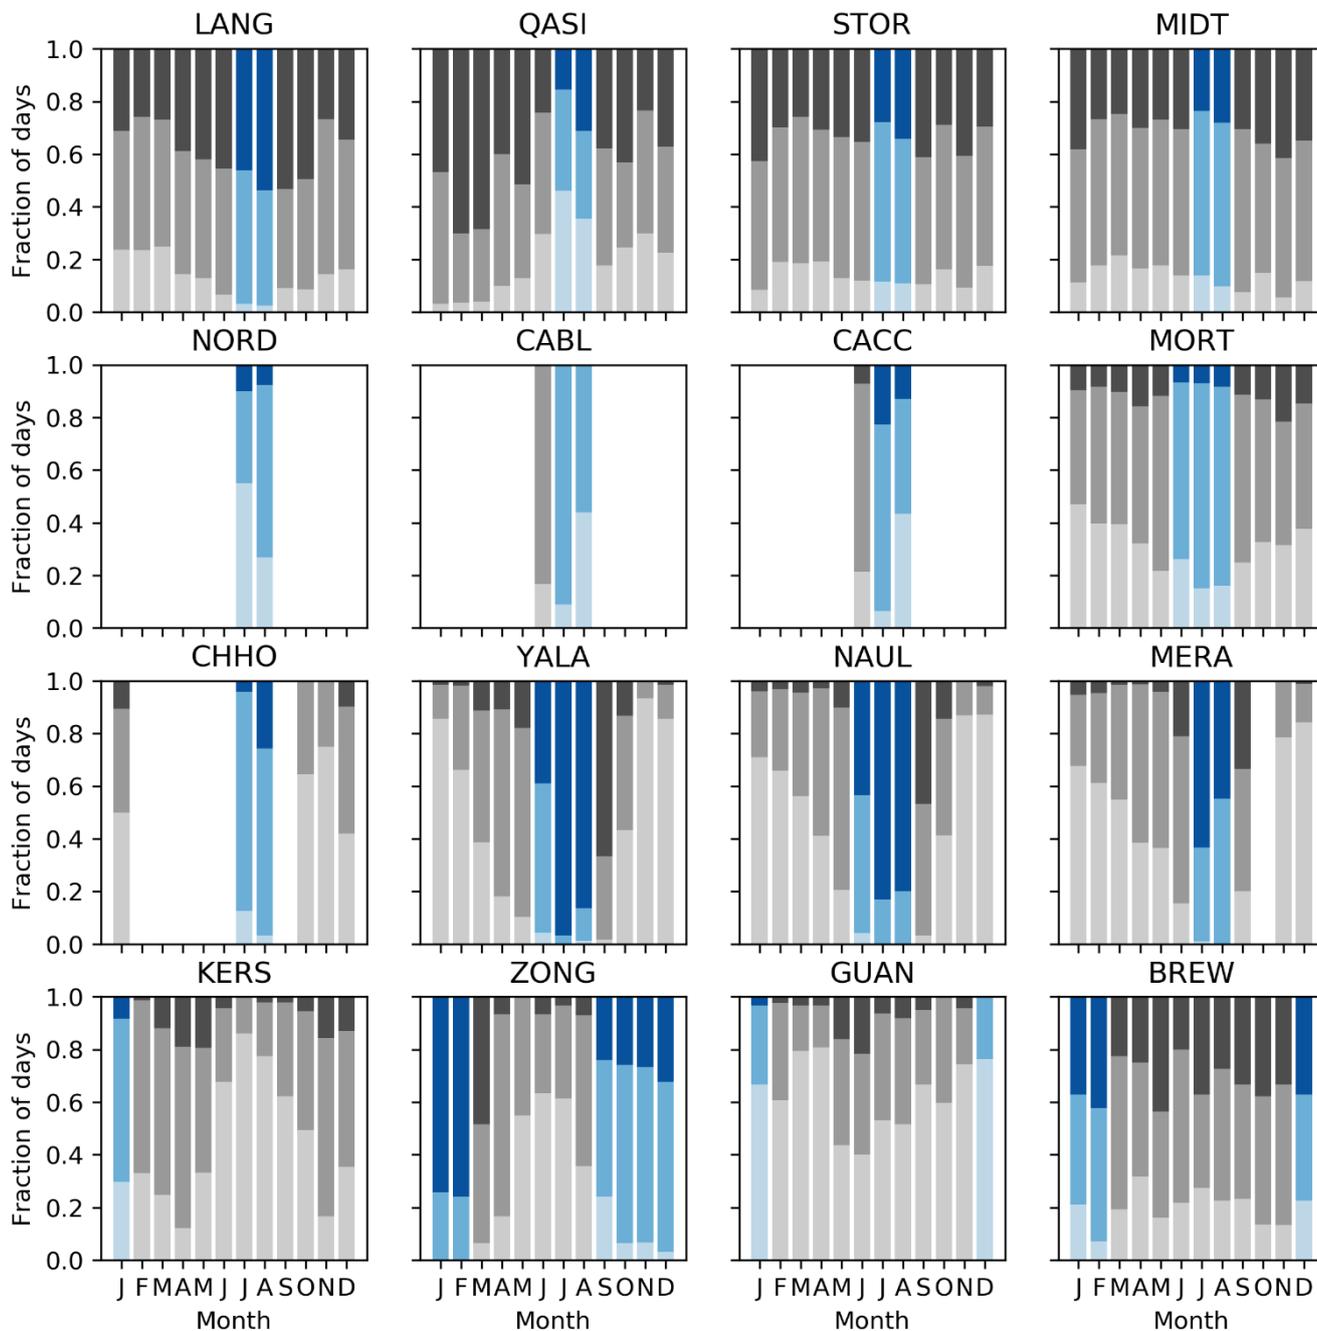

Figure A5: Average melt season SEB terms during hours with surface melt for different cloud conditions (N_e).

675

Figure A6: As for Figure 5 but showing months selected with > 80% of maximum monthly-average Q_M .
