Abstract. Firn from an ice cave in the highest mountain of Greece, Mt. ~~Olympos~~Olympus, was sampled and analysed to determine the tritium content in order to estimate rates of accumulation and to date the ice plug. The presence of a sharp ~~raise of~~ tritium ~~peak~~ content ~~because of indicating~~ the nuclear testing era was expected to be preserved into ice beds. Tritium concentrations were found to vary from 0.9 to 11 TU. This peak did not appear in the analysed samples providing an upper age estimation limit of less than 50 years—for the oldest sampled layer. It is suggested that the rate of melting is responsible for the absence of older firn layers.

1 Introduction

Ice caves or caves hosting perennial ice accumulations (~~Persoiu and Lauritzen, 2017~~)(~~Persoiu and Lauritzen, 2018~~) in Greece are scattered throughout the country's latitude. In total, 76 records of ice caves in Greece have been processed according to ~~Luetscher and Jeannin (2004)~~Luetscher and Jeannin (2004) classification scheme and examined according to ~~their morphology and distribution by Lazaridis et al. (2018)~~climatological criteria and particularly the prevailing air dynamics and glaciological characteristics, such as the type of ice, by Lazaridis et al. (2018). In Mt. ~~Olympos~~Olympus, which is the highest mountain of the country, all the ice caves are classified as 'static with firn', where 'static' is interpreted as single entrance caves that form single down-sloping conduits. Ice of these caves, particularly the ones on the Eastern slopes of Olympus, ~~have~~has been exploited for years between the end of ~~the 19th centuries~~Century and the ~~post-WWII years~~1950s, to provide ice ~~columns~~to villages and ~~town at~~owns in the foothills of the mountain and across the southwestern Greek Macedonia.

In order to determine how old is the firn accumulation in these caves, measurements of the concentration of tritium in the ice were ~~applied~~carried out at the Christaki Pothole in Mt. ~~Olympos~~Olympus. Tritium is a hydrogen isotope that decays emitting beta particles of very low energy ($E_{max} \sim 18.6$ keV) with a half-life of ~~12.33 y~~ 4500 ± 8 days (Lucas ~~&~~and Unterweger, 2000; ~~Ehhalt et al., 2002~~). Tritium is produced in the upper atmosphere by the interaction of cosmic rays with the atoms of the atmosphere. This mechanism introduces tritium into the water cycle by the form of tritiated water and the normal concentration of tritium in precipitation is found to be 5-10 TU (Tritium Units, $1\text{ TU} = 0.11811919$ Bq/L, Terzer-Wassmuth et al., 2022).

During late '50s and early '60s nuclear era, hydrogen bomb detonations introduced huge amounts of tritium into the atmosphere, resulting ~~to~~in a sharp peak of tritium concentration in precipitation all over the world, (Martell, 1963), especially in the northern hemisphere ~~resulting in where~~ tritium concentrations ~~were increased~~ up to 6,000 TU in Canada (Cauquoin et al., 2016) ~~since and Austria, reached in 1953-1963 and in Austria since 1961., respectively~~ (Cauquoin et al., 2016). In Greece, a maximum of 3,550 TU was observed ~~also~~ in 1963. ~~These~~The tritium peaks of tritium in the precipitation of these years (the early 60s) ~~, is~~1960s, are expected to be preserved in ice ~~columns~~sections, if they have not melted since then. ~~Previous studies have dated ice deposits by using the tritium peak, which was either present (Kern et al., 2009) or absent (Kern et al., 2011).~~

40 2 Cave description and geological setting

The cave under investigation (Fig. 1; and supplementary information) is located on the NW slope of ~~the mountain~~Mount Olympus (N40.06898 E22.31350) at an altitude of 2,350 m, very close to the Christaki refuge. The sampling cave is included in the ~~list~~cadaster of ice caves in Greece under the name Christaki Pothole (Lazaridis et al., 2018)(Lazaridis et al., 2018). The ~~first descent in entrance of the cave~~pit is about ten meters and continues with ~~an inclined~~the floor ~~inclining~~ to the west. Most of the cave is covered by an ice plug that overlies limestone gravels and small blocks. The ice plug consists of accumulated firn and snow. When surveyed, it was 1.5 m thick below the entrance and progressively ~~goes thicker to the west~~thickening westwards, reaching ~~about 4.5 m of a maximal~~ thickness. ~~Due to this of 4.5 m. The ice plug prevents any possible access to the westward~~ continuation of the cave ~~to the west, becomes inaccessible~~. The cave is hosted in the Cretaceous crystalline limestones with dolomite interferences (Latsoudas and Sonis, 1985)(Latsoudas and Sonis, 1985). The limestone sequence has a total thickness of about 2,650 m and ~~is consisted~~consists of limestones that gradually ~~reduce their composition~~transits to dolomite. While the eastern slopes of ~~Olympos~~Olympus are affected by the maritime air masses, the western slopes of Mount Olympus act as a barrier to the hot and humid ~~gas~~westerly air masses ~~coming from the west, which increases the amount of and thus experience enhanced orographic precipitation on these slopes~~. Ice caves in Greece are directly influenced by the prevailing climatic conditions (Perşoiu et al., 2021). The amount of precipitation in combination with the high altitude, leads to a ~~high average annual snowfall~~snowfalls even during summer season (Sahsamanoglou, 1989).

Ground-plan with the sampling site depicted and 3d representation of the cave. Other mountains of Greece with ice caves are depicted on A.**

3 Sampling and methods

65 On 23rd of September 2017, forty-one (41) ice samples were collected from the Christaki Pothole. Each sample was collected from a 2 m high section of ~2 m high (Figure 1B), with a portable cup drill of 5cm diameter and about 2-3 cm depth, resulting in samples of 30 to 40 cm³, in 5 cm intervals and spanning from the top of the ice column section to the cave floor. Samples with odd numbering were chosen to be measured/selected for tritium content determination. Measurements were performed at the Archaeometry Center of the University of Ioannina.

70 Tritium measurements were conducted in a Liquid Scintillation Analyzer (TR/SL 3700 Tricarb, Perkin Elmer). Eight ml of For each sample, 8 mL of melted ice sample, without electrolytic enrichment were added in a low-potassium borosilicate glass vial of 20 ml capacity and 12 ml of Ultima Gold LLT scintillation cocktail were added. The vial was closed and shaken to homogenize the solution and was measured for 1400 min typically. Background was also recorded at the same batch of samples. In order to establish the detection limit of the method, several background measurements were pooled and a mean value of 1.200 ± 0.006 cpm were selected as the representative value. The detection limit was calculated using the equation

DL = $\frac{3 \cdot \sigma_B}{\text{eff} \cdot V \cdot 60 \cdot 0.11919}$ (TU), where $\sigma_B = 0.006$ cpm is the uncertainty for the background, $\text{eff} = 0.26$ the efficiency of the detector,

75 $V = 0.008$ L the volume of the sample, 60 for min to sec and 0.11919 Bq/L=1 TU. The calculated value was DL=1.42 TU.

4 Results and discussion

When extracted from the ice column the samples displayed indistinguishable ice. The lack of well distinguished layers and thus it was impossible to make a direct precluded the estimation of the age of the ice in the column. Samples extracted from the ice deposit, by layer counting. However, during the sample processing the samples, it was revealed that almost every ice sample contained remains of dust and soil, as a which is the result of the surface debris deposited during the yearly cycle of snow accumulation during winter and partial melting during summer. The ablation of the surface and the burden of each layer caused the incineration of the debris into the ice mass of each layer. Thus, it is suggested that the maximum layer thickness should not exceed that thickness corresponding to about 40 of annual firm accumulations in the ice column where the samples were collected. Since the ice column of the cave is firm deposit was thought to behave been accumulated for many decades of years, it was assumed possible to find hypothesized that the above-mentioned peak of atmospheric tritium raise in the atmosphere as an abrupt increase in the tritium concentration peak would be found in the melted ice samples. Instead, tritium concentrations were found to vary only from 0.9 to 11 TU, which could be attributed to different initial tritium concentrations in snow falls snowfall. In comparison with tritium concentrations for selected years before the sampling year (2017), most of the tritium concentrations, corrected for decay, could be resulted result from precipitation up to 50 years before sampling year, which corresponds to the calendar year 1967, when the mean annual mean tritium content was in the range of 130-230 TU (Fig. 2, Table S2).

95 Figure 2. Tritium concentration: (a) Annual mean values of tritium in rain samples from various monitoring stations in Greece (GNIP, IAEA), see Fig.1 for the sites of the stations and Table S3 for the coordinates and altitude. (b) Annual mean tritium values of line (a) corrected for decay at the year of ice sampling (2017). (c) Tritium content in ice samples, of odd numbering, with depth, from the Christaki pothole.

Also, these measurements could not be attributed to ice beds deposited before the '50s, because in that case higher concentrations remaining from the high tritium concentrations during early '60s should have been preserved into some of the measured samples. This gives an upper limit of the possible age of the ice layers that were sampled during the campaign of September 2017. -Considering ~~that for~~ this upper limit of 50 years for the ~~base of ice layers aged~~ deposit, the corresponding mean ~~winter snow~~ ice layer thickness ~~of each layer should be~~ at least 4 cm y⁻¹; the result is in accordance with the presence of debris in almost each sample, as well as with findings in other ice caves. In Monlesi Ice cave, Switzerland, an annual accumulation rate 7-11 cm y⁻¹ was estimated based on tritium and ~~radon~~²¹⁰Pb measurements (~~Luetscher et al., 2007~~)(Luetscher et al., 2007) and in Ledena Pit, a ~~erroatian~~Croatian ice cave, an average accumulation rate of up to 12 cm y⁻¹ during period of 1963-1995 was also estimated (Kern et al., 2008)(Kern et al., 2008). However, these ~~estimations~~ estimates do not date the ~~time when onset of cave glaciation, nor times at which the cave started to function as an~~ may have been completely ice cave ~~nor to an event of total ice melting in the meanwhile~~. free. The ice surface ~~that plug in ice caves melts when it is~~ in contact with the ~~cave walls~~ bedrock (Bella and ~~floor is melting in non-permafrost areas such as Greece~~. Zelinka, 2008; Telbisz, 2019). Thus, the results are rather indicative of a melting rate that cannot support the preservation of ice that is older than 50 years. ~~However, in deeper inaccessible parts of the cave older ice may be preserved.~~

5 Conclusions

The Christaki Pothole provided a two meters thick succession of ice samples that display relatively low concentration of tritium, without any pattern of an abrupt increase that could correspond to the tritium peak due to hydrogen bomb detonations in early '60s. This indicates that accumulated firn beds ~~are were~~ younger than fifty years ~~before in~~ 2017. The absence of earlier beds is suggested to be the result of melting rate at the bottom of the ice plug or may occur in ice beds that are not accessible due to the morphology of the Christaki ~~pothole~~Pothole.
