Abstract.

The Los Alamos sea ice model (CICE) is being tested in standalone mode to identify biases that limit its suitability for seasonal prediction, where CICE is driven by atmospheric forcings from the NCEP Climate Forecast System Reanalysis (CFSR) and a built-in mixed layer ocean model in CICE. The initial conditions for the sea ice and mixed layer ocean are also from CFSR in the control experiments. The simulated sea ice extent agrees well with observations during the warm season at all lead times up to 12 months, in both the Arctic and Antarctic. This suggests that CICE is able to provide useful sea ice edge information for seasonal prediction. However, the model's Arctic sea ice thickness forecast has a positive bias that originates from the initial conditions. This bias often persists for more than a season, which limits the model's seasonal forecast skill. To address this limitation, additional CS2_IC experiments were conducted, where the Arctic ice thickness was initialized using CryoSat-2 satellite observations while keeping all other initial fields the same as in the control experiments. This reduced the positive bias in the ice thickness in the initial conditions, leading to improvements in both the simulated ice edge and thickness at the seasonal time scale. This study highlights that the suitability of CICE for seasonal prediction depends on various factors, including initial conditions such as sea ice thickness, oceanic and atmospheric conditions in addition to sea ice coverage. By reducing the bias in the initial ice thickness, CICE has the potential to improve its seasonal forecast skill and provide more accurate predictions of sea ice extent and thickness.

1 Introduction

Sea ice concentration observations from passive microwave satellites reveal that the Arctic has experienced a rapid decline in ice coverage over the past few decades, making it the region with the greatest warming on Earth (Chapman and Walsh, 2003; IPCC, 2014). Global climate models suggest that further decreases are expected in the coming years (e.g., IPCC, 2014, 2021). Sea ice plays a crucial role in the regional energy balance and the global climate as a whole. Acting as a thin material layer between the atmosphere and ocean, sea ice amplifies radiative feedback with its higher surface albedo compared to open water (e.g., Holland and Bitz, 2003; ACIA, 2005; Dethloff et al., 2006), making it a sensitive and visible indicator of climate change. Reliable sea ice prediction is essential not just for the polar regions but also for improving predictability in mid-latitudes at subseasonal to seasonal (S2S) time scales due to teleconnections (e.g., Randall et al., 1998; Jaiser et al., 2012; Li et al., 2014).

25 Identifying sources of predictability for weather at S2S time scales is challenging. However, sea ice has shown promise
due to its seasonal anomaly persistence (Blanchard-Wrigglesworth et al., 2011a; Holland et al., 2011; Smith et al., 2016;
Bushuk et al., 2019). Recent advances in sea ice modeling offers potential for improving both medium-range and climate
predictions (e.g., Wang et al., 2013; Hebert et al., 2015; Guemas et al., 2016; Chevallier et al., 2017). Weather predictions
from a numerical model incorporating a sea ice model are found to be more skillful compared to those based on Arctic sea
30 ice persistence (Grumbine, 2003; Hebert et al., 2015). The accuracy of sea ice initial conditions is critical to seasonal sea ice
forecast (Holland et al., 2011; Blanchard-Wrigglesworth et al., 2011b; Wang et al., 2013). In particular, the fidelity of sea ice
thickness initialization is important as thickness has greater persistence than concentration (Krinner et al., 2010; Chevallier and
Salas-Mélia, 2012; Day et al., 2014a; Collow et al., 2015; Allard et al., 2018; Blockley and Peterson, 2018). Furthermore, sea
ice predictability is season-dependent (Holland et al., 2011; Day et al., 2014b; Bushuk et al., 2020) and the predictability of
35 minimum sea ice extent depends on spring and early summer atmospheric conditions, as well as the inclusion of melt ponds
(Liu et al., 2015; Schröder et al., 2019; Bushuk et al., 2020).

The Los Alamos Community Ice Code (CICE; Hunke et al., 2015) has been selected to be integrated into NOAA's Unified
Forecast System (UFS) as the next operational coupled atmosphere-ocean-seaice-land system for S2S predictions. Due to the
fact that CICE was originally developed for long-term climate research, its suitability for seasonal forecasting needs to be
40 assessed. Hunke et al. (2020) highlighted the challenges in adapting sea-ice modeling intended for long-term research to short-
term forecasting. This study aims to examine the performance of CICE in seasonal forecasting as a complementary effort.
To avoid various feedbacks involved in a fully coupled atmosphere-ocean-sea ice model, we decided to first assess CICE in
standalone mode. Evaluating CICE's skill in this controlled environment allows for a detailed analysis of sea ice conditions.
For instance, in standalone mode, Schröder et al. (2019) found the default conductivity coefficient in CICE to be too low
45 at colder temperatures. The objective of this study is to identify biases that limit the seasonal prediction skill of CICE and
establish a consistent set of baseline sea ice forecasts for future studies that incorporate sea ice into coupled atmosphere and
ocean modeling. Furthermore, the impact of biases in sea ice thickness initialization on forecast skill is investigated. The
experimental setup is described in detail in section 2. The basin-wide and regional performance at different lead times, as well
as with different initializations, are presented in section 3, followed by a discussion in section 4.

50 2 Model Setup

In this study, we utilized version 5.1.2 of the CICE (Hunke et al., 2015), a dynamic-thermodynamic sea ice model originally
designed for use in global climate models. CICE simulates the growth, melting, and movement of sea ice in the cold regions
and includes a subgrid-scale ice thickness distribution. The model uses the Elastic-Viscous-Plastic (EVP) rheology for ice
dynamics (Hunke, 2001), as well as the ice strength parameterization for the ridging scheme (Lipscomb et al., 2007). Our
55 experiments adapted standard five ice thickness categories (a low bound thickness of 0., 0.64m, 1.39m, 2.47m and 4.57 m,
respectively), with four ice layers and one snow layer in each thickness category. A linear function of salinity for the freezing
temperature was employed. A detailed description of the CICE model is available at Hunke et al. (2015).

The CICE experiments conducted in this study were performed in the global domain, utilizing a combination of an Arctic bipolar grid projection and a Mercator projection for the rest of the globe, as shown in Fig.1 of Bleck and Sun (2004). The experiments employed a horizontal resolution of 15 km at the North Pole and 30 km at 60°N and 60°S. The bathymetry data from ETOPO1 (Amante and Eakins, 2009) are interpolated onto the model's global compound grid. A time step of 900 seconds is used in all model experiments.

2.1 Atmospheric Boundary Conditions

The atmospheric boundary forcings used in this study are derived from the 6-hourly archives obtained from CFSR¹ (Saha et al., 2010), which include downward surface radiation of both shortwave and longwave components, 10 m wind speed, 2 m temperature, 2 m specific humidity, and precipitation, which is further broken down into rain and snow. The data covers the period from 2011 to 2017 and has a spatial resolution of 0.2°. A pre-processing step was undertaken to horizontally interpolate these variables onto the compound model grid.

2.2 Ocean Boundary Conditions

CICE requires information on the sea surface temperature (SST), which can be either prescribed directly or generated using the built-in mixed layer ocean model within CICE. Initially, the CFSR SST data was used to drive the CICE model. However, it was discovered that this approach resulted in an unrealistic increase in basal melt due to a small positive bias in the CFSR SST data. To address this issue and ensure consistency between the SST and the ice state, an alternative method was adopted, i.e., to use the mixed layer ocean model within CICE to prognose the SST. This means that the CICE model itself generates the SST information based on the physical processes happening within the mixed layer of the ocean. By employing this approach, the SST and ice state remain consistent, allowing for a more reliable representation of the interaction between the sea ice and the ocean in the model simulations than the earlier attempt. However, it's important to note that the mixed layer ocean model used in this approach is a simplified 1-dimensional model that does not include horizontal advection in the ocean. This limitation does impact the model results, as will be demonstrated later.

During the model integration, the temperature at the interface between the ice and ocean is maintained at the freezing temperature of the mixed layer. In case there is any excess energy remaining after the ice and snow have melted, it is transferred to the ocean mixed layer. The thickness of the mixed layer ocean model is held constant at 20 meters.

2.3 Initial Conditions

The control experiments utilized the CFSR reanalysis to initialize both the ice and the ocean states. The sea ice concentration and sea ice thickness were obtained at 0.2° resolution, and sea surface temperature and sea surface salinity were obtained at 0.5° resolution. All these data were interpolated onto the compound model grid.

¹available at <http://rda.ucar.edu/datasets/ds094.0>

Table 1. Details in two sets of CICE experiments.

Experiments	Atm Boundary Conditions	Initial Conditions for Ice & Ocean	Initialization Months
Control Runs	CFSR	CFSR	Apr 2011 – Dec 2017
CS2_IC Runs	CFSR	Same as in control, except initializing the Arctic with CryoSat-2 ice thickness	Oct-Apr 2011-2017

CryoSat-2 satellite observations have provided another source of estimates for Arctic ice thickness (Laxon et al., 2013; Ricker et al., 2014; Grosfeld et al., 2016) since 2011 during the boreal winter months from October to April. In order to explore different initial conditions, additional experiments were conducted where the ice thickness was initialized with CryoSat-2 data, despite the inherent uncertainty in the dataset regarding thin ice (Ricker et al., 2017), as no other datasets were available at that time. The remaining initial conditions, such as snow depth over the sea ice and atmospheric boundary conditions, kept consistent with those used in the control experiments. These experiments utilizing the CryoSat-2 initialization are referred to as "CS2_IC".

It is important to highlight that the original CryoSat-2 dataset does not provide ice thickness data in the immediate vicinity of the North Pole. To address this limitation, we estimated ice thickness values in this region by utilizing the surrounding ice thickness data. This interpolation process allowed us to fill the data gap and utilize the interpolated values as the model's initial condition. In the CICE initialization, the CryoSat-2 ice thickness was treated as a single category at each grid point. Since the CryoSat-2 data is limited to the Arctic, the initial sea ice thickness for the Antarctic region in the CS2_IC experiments was still derived from the CFSR dataset. Furthermore, in order to ensure consistency in the initialization of both sea ice concentration and thickness, grid points with no sea ice concentration in CFSR or sea ice thickness in CryoSat-2 were assigned zero values for sea ice concentration and thickness respectively.

The control experiments were initialized on a monthly basis from April 2011 to December 2017, whereas the CS2_IC experiments, which initialized with CryoSat-2 Arctic ice thickness, were carried out monthly during the boreal cold season (October to April) from 2011 to 2017, as presented in Table 1. The integration period for all model experiments was 12 months.

3 Model Results and Verification

In this study, the forecast skill was evaluated by comparing the simulated monthly mean of sea ice concentration and thickness with observations and reanalysis data for the matching time period. The evaluation was conducted using root-mean-square error (RMSE) and bias. All comparisons and verifications are conducted on the native grid, except for overall evaluations at the hemispheric or regional scales. The monthly averages of all fields presented are centered on the stated lead time. Lead times not ending in ".5" are rounded up to the nearest integer month for simplicity (i.e., 11.5-month lead time is rounded up to 12-month lead time).

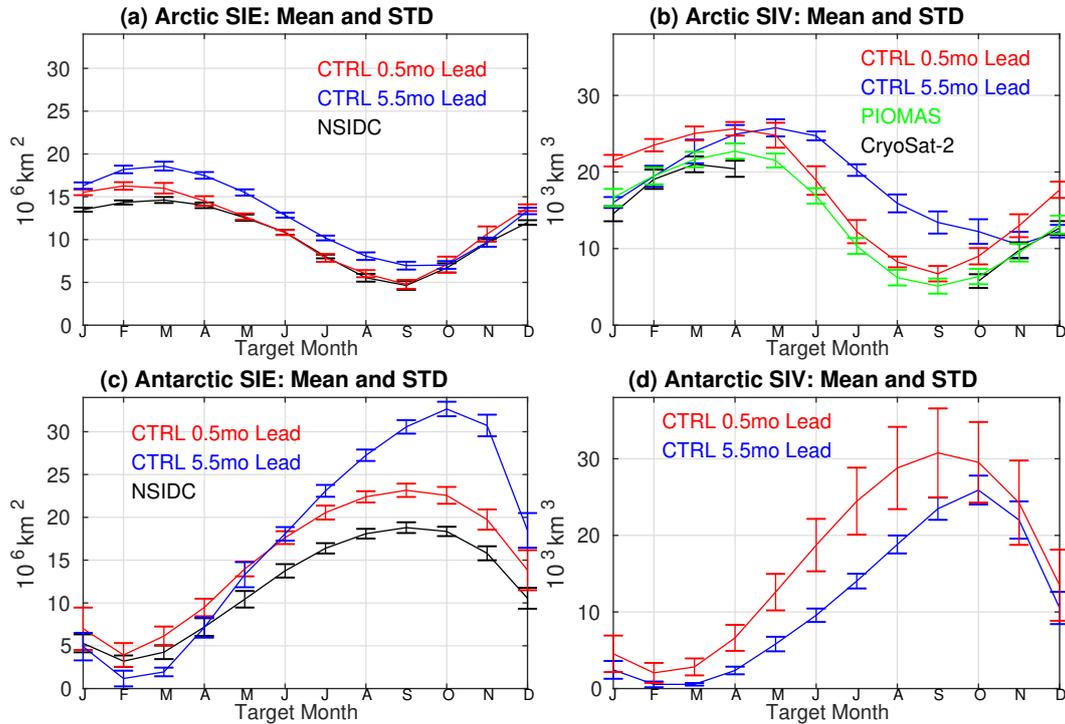

Figure 1. Upper: mean and standard deviation of sea ice extent (SIE) at each target month from forecasts at 0.5-month and 5.5-month lead times in the control experiments and NSIDC observations. Averaged over 2011-2017. Lower: same as upper, except for sea ice volume (SIV) with CryoSat-2 observations and PIOMAS reanalysis. Left: Arctic; Right: Antarctic.

3.1 Hemispheric Scales

Sea ice extent (SIE) is defined as the area of the ocean with at least 15% of sea ice cover, which provides a reliable approximation of the sea ice edge. Fig. 1 presents the simulated SIE and sea ice volume (SIV) in the Arctic and Antarctic in the control experiments at lead times of 0.5-month (1st-month average) and 5.5-month (6th-month average) for each target month. It also shows the monthly SIE from the National Snow and Ice Data Center (NSIDC), which is based on passive microwave satellite sensors (Meier et al., 2012). Additionally, SIV observations from CryoSat-2 and SIV reanalysis from the Pan-Arctic Ice Ocean Modeling and Assimilation System (PIOMAS, Schweiger et al., 2011) are included. The curves represent the 2011-2017 average and are marked with their standard deviation during this time period.

Fig. 1(a) shows the Arctic SIE forecast matches NSIDC observations better during the warm season than the cold season, at both 0.5-month and 5.5-month lead times. The modeled interannual variabilities of the Arctic SIE, as shown by the standard deviation, appear similar across all seasons and match those in NSIDC well. In Fig. 1(b), the Arctic SIV forecast at a 0.5-month lead time is similar to CryoSat-2 observations or PIOMAS reanalysis in the warm season and higher than these two products in the cold season. The biggest positive bias in SIV at a 5.5-month lead time is shifted to the warm season, suggesting that the

bias in the SIT initialization in the cold season persisted for more than a season. The increasing model bias in SIE and SIV with lead time beyond seasonal time scale clearly limits the CICE model's seasonal application.

Fig. 1(c) shows that the modeled Antarctic SIE has a positive bias compared to NSIDC observations at a 0.5-month lead time in all seasons, where the biggest bias occurs in austral spring, similar to the Arctic. A bigger positive SIE bias is seen in
130 austral spring at a 5.5-month lead time. The interannual variabilities in the Antarctic SIE are generally larger than those in the Arctic, both in models and observations.

In Fig. 1(d), the modeled Antarctic SIV exhibits a minimum/maximum in February/September at a 0.5-month lead time, as opposed to in March/October at a 5.5-month lead time. The delay peak of the minimum/maximum at longer lead times, as observed in the Arctic, suggests a modeling system bias that remains unclear without Antarctic SIV observation or reanalysis.
135 Additionally, the fact that the Antarctic exhibits a bigger SIE bias than the Arctic may be due to the rudimentary ocean representation in the mixed-layer ocean model used in the standalone setup, which ignores horizontal transport in the ocean.

Fig. 2 displays the RMSE in Arctic SIE compared to NSIDC observations for the control and CS2_IC experiments, averaged over the period 2011-2017. The upper panel shows the RMSE for each target month at lead times up to 12 months, as well as the difference between the two model experiments. White spaces indicate the absence of model data due to the unavailability
140 of CryoSat-2 data for model initialization between May and September. The results indicate that, in the control experiments, the lowest RMSE in Arctic SIE occurs during summer and fall at all lead times up to 12 months, while the largest RMSE occurs during late winter and early spring at lead times longer than 3 months. In the CS2_IC experiments, where the model is initialized with the CryoSat-2 ice thickness dataset, the RMSE in Arctic SIE is reduced to varying degrees across most seasons.

The lower panel of Fig. 2 presents the RMSE in SIV compared to the PIOMAS reanalysis. The results indicate that in the
145 control experiments, SIV is consistently overestimated in all months compared to PIOMAS, with positive bias persisted across most lead times and target months, albeit at varying magnitudes. The most notable bias appears in the 'summer barrier' of Fig. 2(d), where skill reemerges prior to winter initialization at a longer lead time. The CS2_IC experiments show a marked reduction in the overall positive SIV bias, especially in summer and fall with winter and spring initializations.

Despite a broad reduction in SIE and SIV prediction biases through CryoSat-2 ice thickness initialization, the bias pattern in
150 the CS2_IC experiments remains similar to that of the control experiments. The most significant SIV bias occurs in the warm season, while the most substantial SIE bias occurs in the cold season, at lead times of 4-7 months. This pattern is related to the uncoupled experimental setup, where oceanic heat transport is absent. Furthermore, the CryoSat-2 dataset itself may also contribute to the biases, as relative uncertainties are high over thin ice regimes, as sea ice thickness is determined by the ice surface above the sea level (Ricker et al., 2017).

Fig. 3 presents the RMSE in Antarctic SIE compared to NSIDC observations for the control experiments during the period
155 2011-2017. The results indicate that SIE forecasts are in good agreement with observations at all lead times for austral summer and especially fall when SIE reaches its annual minimum. The highest RMSE in seasonal forecast occurred in austral spring at its annual maximum, similar to the pattern in the Arctic. The Antarctic exhibits an austral 'spring barrier' in skill with austral fall and winter initialization, similar to the 'summer barrier' seen in the Arctic.

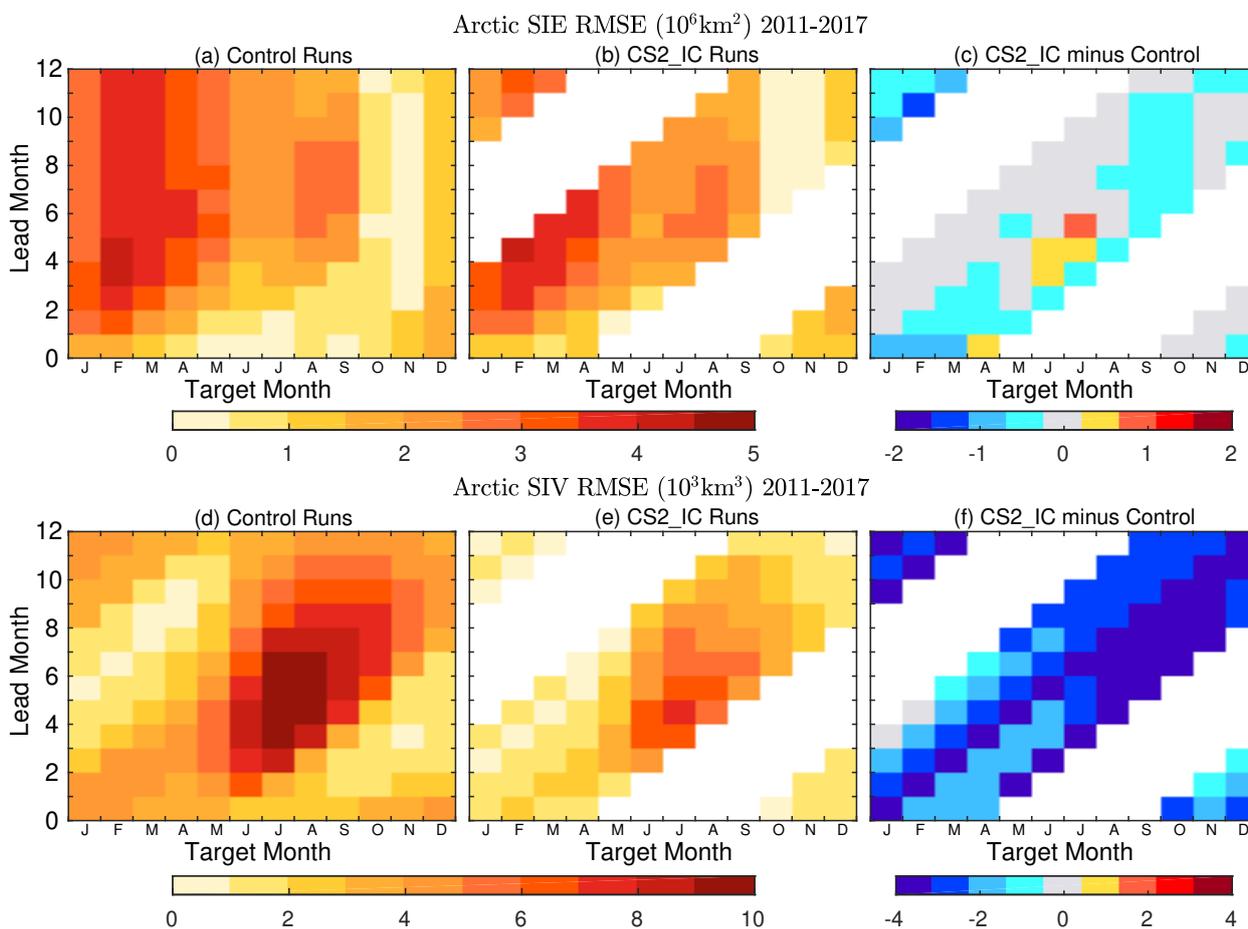

Figure 2. Upper: root mean square error (RMSE) in the Arctic sea ice extent (10^6 km^2) with respect to NSIDC at lead times up to 12 months against the target month in the control [left, (a)] and in the CS2_IC experiments [middle, (b)] and the difference of (b) and (a) (right). Averaged over 2011-2017. Lower: same as upper, except for sea ice volume (10^3 km^3) w.r.t. PIOMAS. White spaces indicate no model data due to lack of CryoSat-2 data for model initialization from May to September.

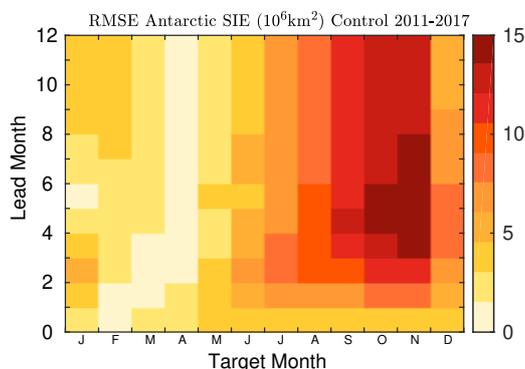

Figure 3. RMSE in the Antarctic sea ice extent w.r.t. NSIDC in the control experiments at lead times up to 12 months against the target month. Averaged over 2011-2017.

160 3.2 Pan-Arctic forecasts at 6-month lead time

Fig. 4 displays the Arctic sea ice concentration (SIC) in the control and CS2_IC experiments, which were used to investigate the evolution of sea ice distribution. The figure shows the SIC during initialization on April 1, 2016, the forecast for October 2016, and the corresponding AMSR2 satellite observations (Spreen et al., 2008). The initial SIC in both experiments closely matched the AMSR2 observations. By month 6, the control experiment exhibits a positive SIC bias, primarily in the Beaufort, 165 Chukchi and East Siberian Seas, whereas the SIC from the CS2_IC experiment was closer to AMSR2. This discrepancy can be attributed to the difference in sea ice thickness (SIT) shown in Fig. 5 from the same experiments in Fig. 4. Specifically, the control experiment had ice up to 3 m thicker than the CryoSat-2 observations in the region poleward of the Beaufort and Chukchi Seas in the springtime, leading to a positive SIT bias that persisted in this region six months later (lower left panel).

The positive bias in SIT in the CFSR products presented here is consistent with the findings by Collow et al. (2015). As noted 170 in Saha et al. (2010), SIT is not assimilated in the data assimilation system used in CFSR due to the lack of SIT observations. This bias in SIT can lead to errors in both SIT and SIC in the seasonal forecast, as seen in Figs 4 and 5. The CS2_IC experiment was able to reduce this initial bias, resulting in improved forecasts of both SIT and SIC. This outcome is in line with previous studies that have shown the positive impact of realistic sea ice thickness initialization on forecast skill (e.g., Day et al., 2014a; Collow et al., 2015; Dirkson et al., 2017; Allard et al., 2018; Blockley and Peterson, 2018; Schröder et al., 2019).

175 3.3 Pan-Arctic 12-month forecasts

Fig. 6 shows the SIT in the initial conditions on January 1, 2016, along with its forecast for December 2016 in both the control and CS2_IC experiments, and corresponding CryoSat-2 observations. The results are consistent with those in Fig. 5, indicating that in the control experiment, the positive bias in SIT in the initial conditions is primarily accountable for the excessive ice thickness seen in the Beaufort, Chukchi, and East Siberian Seas in the 12-month forecast. In contrast, the SIT 12-month forecast 180 in the CS2_IC experiment is considerably closer to the CryoSat-2 observations than in the control.

Sea Ice Concentration (%)

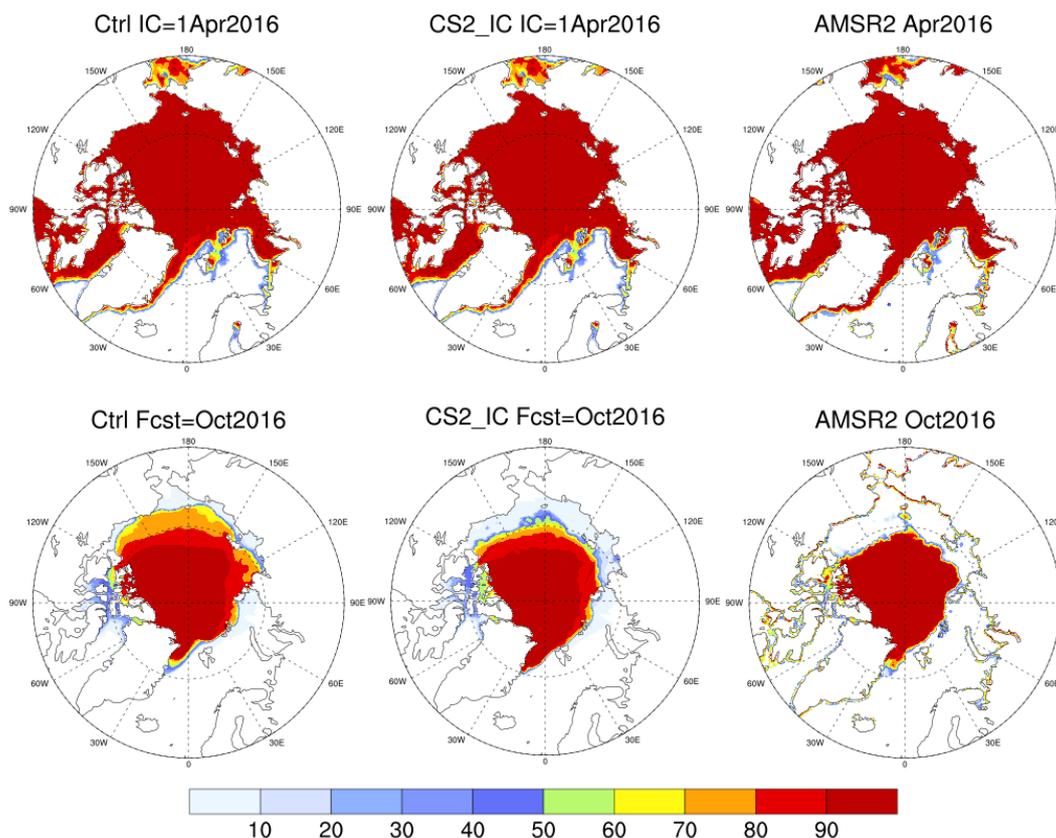

Figure 4. Arctic sea ice concentration (%). Left: initial condition on April 1, 2016 and forecast for October 2016 in the control experiment; Middle: same as left, except in the CS2_IC experiments; Right: corresponding AMSR2 observations.

To investigate the mechanism behind the differences between the two model experiments seen in Fig. 6, we present the simulated Arctic SIE and SIV throughout the 12-month integrations in Fig. 7(a) and (b), as well as their comparison to SIE observations from NSIDC and SIV reanalysis from PIOMAS. The initial Arctic SIE in January is similar in both experiments and higher than the NSIDC observations. The initial Arctic SIV in the CS2_IC experiment is lower than that in the control experiments and closer to PIOMAS reanalysis. The SIE and SIV forecasts in the fall in the CS2_IC experiment end up closer to NSIDC and PIOMAS than in the control experiment. The transitions of SIE and SIV from spring to fall are different in these two experiments, which can be attributed to the area and volume tendencies arising from the thermodynamics and dynamics² in the model archives. The tendency averages north of 67.5°N are shown in Fig. 7(c), where there are more thermodynamics-linked tendencies in both ice area and ice volume than dynamics-linked ones. The negative tendencies in the CS2_IC experiment

²The CICE archives use the variable names 'daiidt' and 'daiidd' for area tendencies from thermodynamics and dynamics, and 'dvidt' and 'dvidd' for volume tendencies from thermodynamics and dynamics, respectively.

Sea Ice Thickness (m)

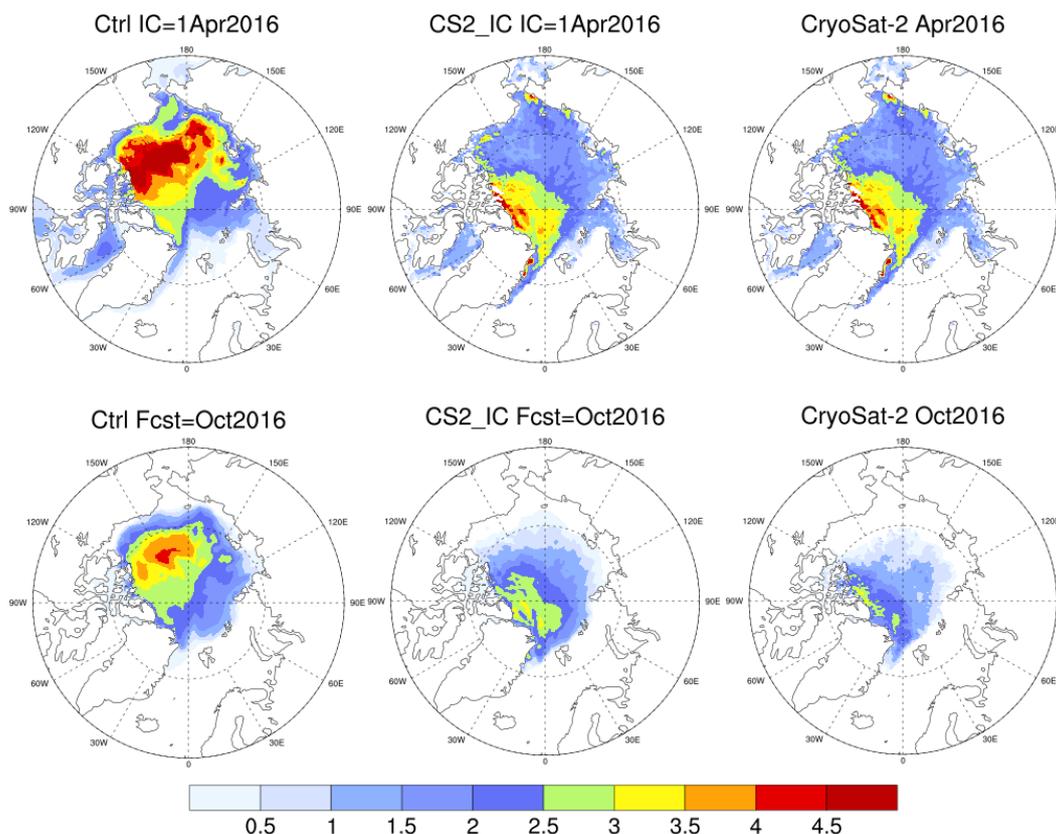

Figure 5. Same as Fig. 4, except for sea ice thickness (m) with CryoSat-2 observations.

190 are slightly larger than those in the control experiment during the warm season. Furthermore, Fig. 7(d) shows the averaged melting rates from snow, top, basal and lateral in both experiments, also north of 67.5°N. The snow melting rate peaks one month earlier than the other rates. In July, the top melting rate is about twice as large as that from the basal melt. The most significant difference in these melting rates between the two experiments is in the basal melt. The CS2_IC experiment, with a higher basal melting rate during summer, yielded both SIE and SIV closer to observations in fall, compared to the control
 195 experiment.

To further investigate the difference in melting rates between the two model experiments, we present the simulated ice concentration and thickness in the control experiment in the left column of Fig. 8. The middle and right columns show the differences in sea ice concentration, sea ice thickness, top and basal melting rates between the CS2_IC and control experiments. These variables are forecast for July 2016 from the runs initialized on January 1, 2016. One dominant feature in the Arctic
 200 between 120°E and 120°W is that both ice concentration and thickness are smaller in the CS2_IC experiment than those in the

Sea Ice Thickness (m)

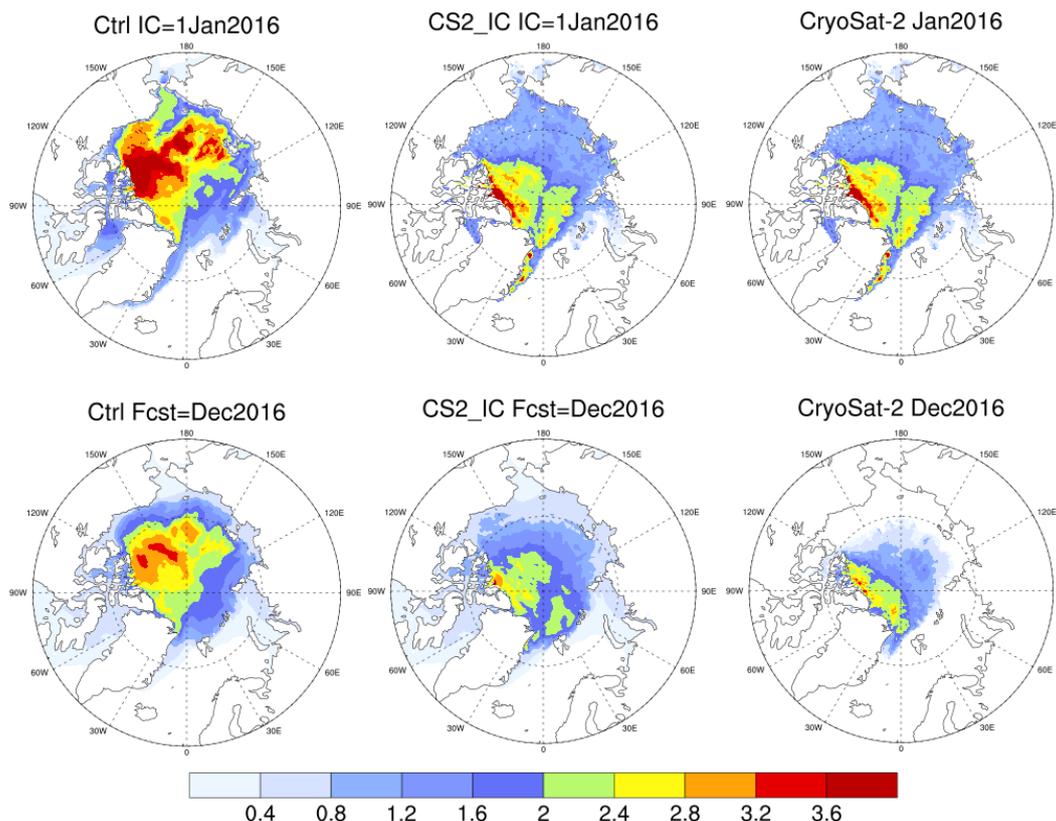

Figure 6. Arctic sea ice thickness (m). Left: initial condition on January 1, 2016 (upper) and forecast for December 2016 in the control experiment (lower); Middle: same as left, except in the CS2_IC experiments; Right: corresponding CryoSat-2 observations.

control experiment. This is consistent with a higher melt rate, both at top and bottom, in the marginal ice zone in the CS2_IC experiment, which appears to be more realistic than in the control experiment.

There is still a positive bias in SIT in the Greenland Sea and central Arctic in the CS2_IC experiment as shown in Fig. 6. Fig. 9 compares the modeled monthly mean SST with the OISSTv2 dataset (Reynolds et al., 2007) for target months April, August and December, at lead times of 4, 8 and 12 months, in the CS2_IC experiment initialized on January 1, 2016. During the cold season, the modeled SST shows a cold bias dominating the Greenland, Iceland, and Norwegian Seas (GINS) as well as the Bering Sea. During the warm season, although there is a warm bias away from the ice edge, a cold bias still dominates the marginal ice zone. This cold bias in the marginal ice zone is attributed to the lack of northward heat transport to the Arctic from the Atlantic and Pacific Oceans, as a simplified column mixed layer ocean model used here doesn't consider ocean currents.

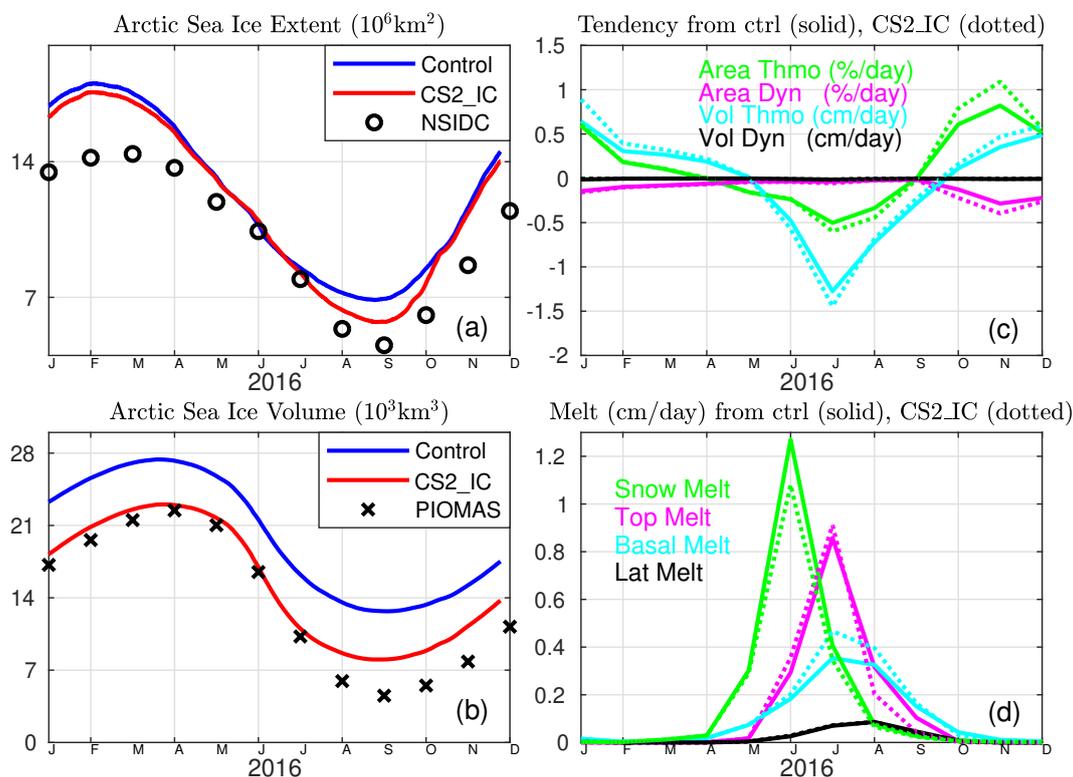

Figure 7. Forecasts of Arctic sea ice extent and sea ice volume up to 12 months initialized on January 1, 2016 in the control and CS2_IC experiments are in (a) and (b) in comparison with NSIDC observations and PIOMAS reanalysis. The corresponding tendency of SIE (%/day) and SIV (cm/day) attributed to ice thermodynamics and dynamics are in (c), and melting rates (cm/day) from snow, top, basal and lateral are in (d) in the control (solid) and CS2_IC (dotted) experiments. Averages north of 67.5°N are shown in (c) and (d).

210 Meanwhile, the positive bias in SIT in the central Arctic could be linked to the colder atmospheric forcings from the CFSR dataset, which are utilized to drive the CICE model in this study.

In summary, the CICE model's seasonal prediction of the Arctic SIE has higher skill in the warm season than in the cold season at almost all lead times in the control experiment. The largest Arctic SIT bias occurs in summer at 3- to 6-month lead times and in fall/winter at roughly 6- to 9-month lead times. due to a thicker ice initialization in the cold season and insufficient melting rates in the warm season. The use of more realistic, thinner ice initialization in the Arctic with the CryoSat-2 observations in the CS2_IC experiments leads to higher forecast skill in both SIE and SIV at all lead times. However, a positive SIV bias still exists in the CS2_IC experiments during summer at 3- to 6-month lead times. Further examination of specific regions in the following section will provide additional insights into this issue.

Forecast July 2016 (IC=1Jan2016)

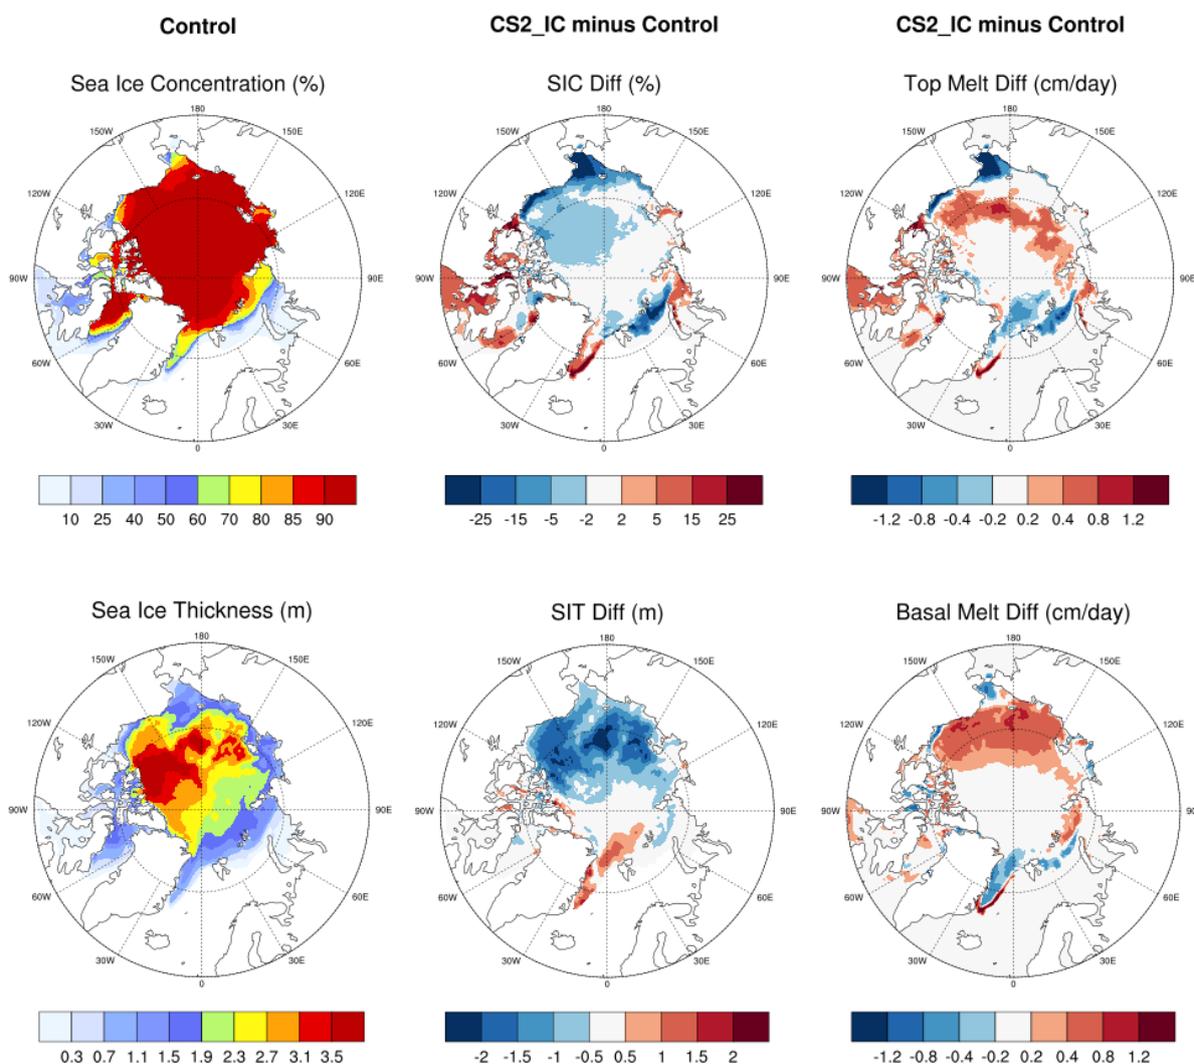

Figure 8. Arctic sea ice concentration (%) and sea ice thickness (m) in the control experiment are shown in the left column. The difference between CS2_IC and control experiments in the sea ice concentration (%), sea ice thickness (m), top and basal melting rates (cm/day) are in the middle and right columns. All are forecast for July 2016 initialized on January 1, 2016.

SST Bias in CS2_IC Run (IC=20160101)

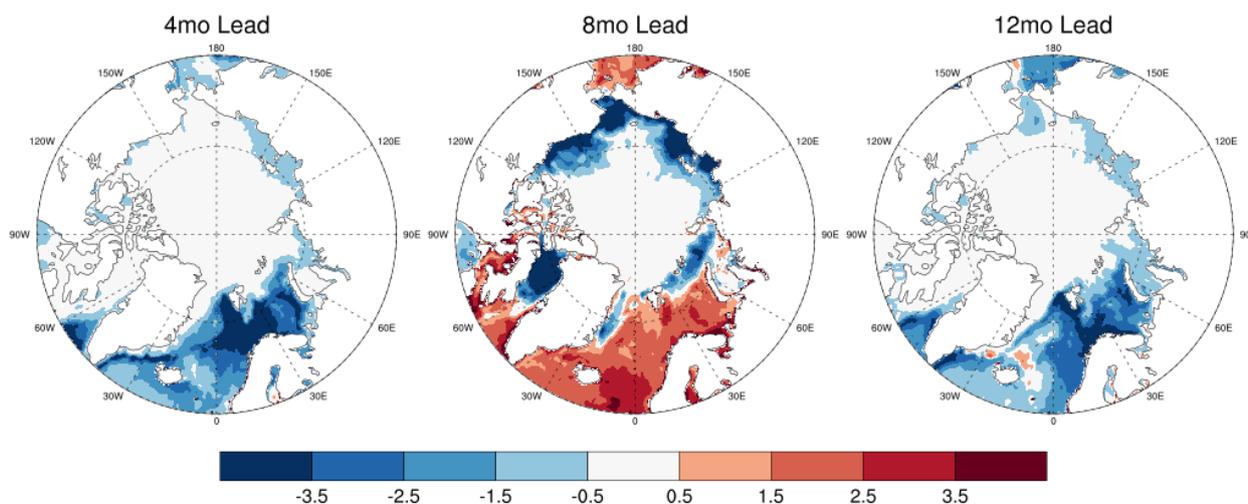

Figure 9. SST bias against OISSTv2 at lead times of 4, 8 and 12 months, respectively, in the CS2_IC experiment initialized on January 1, 2016.

3.4 Regional Scales

220 Analysis of the sea ice prediction skill was conducted in regions defined in Fig. 10, from <https://arctic-roos.org>. For the purpose of this study, we refer to the combination of the Barents, Kara, and Greenland Seas as the BKG seas. To investigate the seasonality of the forecast skill seen earlier, regional SIE and SIV forecasts in the control experiment (solid blue) and the CS2_IC experiment (dashed red) were presented in Fig. 11. These forecasts covered 12-month integrations initialized on April 1, average of 2013 to 2017, the period when AMSR2 observations were available. In Fig. 11(a), SIE in the control
225 experiments was reasonably predicted in most regions in summer and fall, but overpredicted in the BKG Seas, Baffin Bay and the East Siberian Sea in winter at lead times longer than six months. The CS2_IC experiment, initialized with more realistic SIV, showed improved SIE prediction in the East Siberian Sea at lead times above six months. However, there were no notable changes seen in the BKG seas and Baffin Bay.

The corresponding SIV forecasts in these regions from the same experiments were also analyzed, and the results were
230 presented in Fig. 11(b), alongside CryoSat-2 observations. The positive SIV bias in the Beaufort, Chukchi, East Siberian and Laptev Seas seen in the control experiment was largely reduced in the CS2_IC experiments at almost all lead times, indicating that the SIT bias in initialization was the primary cause of the positive SIV bias in the seasonal forecast in this Arctic region between 120°E and 120°W. However, positive biases in SIE in the BKG Seas and Baffin Bay, located in the vicinity of the Atlantic Ocean, remain unchanged.

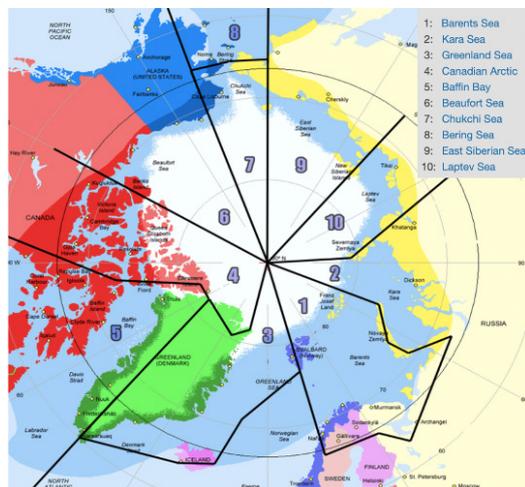

Figure 10. Different regions in the Arctic Ocean. Reproduced from <https://arctic-roos.org>.

235 Fig. 12 presents the regional bias in SIE and SIV, similar to Fig. 11, with model initializations in October, when Arctic sea ice coverage is near its minimum. During winter and spring, when observations are available, the SIE and SIV predictions closely align with AMSR2 and CryoSat-2 observations in most regions. However, both the control and CS2_IC experiments exhibit a positive bias in SIE and SIV in the BKG Seas, Baffin Bay, and the East Siberian Sea. This finding is consistent with Fig. 11, which used April initializations.

240 Comparing the CS2_IC experiments with the control experiments, there is a modest improvement in SIV skill in the Arctic region between 120°E and 120°W. This improvement arises from initializing with a more realistic SIV, as opposed to the control experiments. The benefit of a more realistic ice thickness initialization is more pronounced when initialized from a high SIC state in April, compared to when initialized from a low SIC state in October, since SIV in the CFSR dataset has a bigger bias in April than in October.

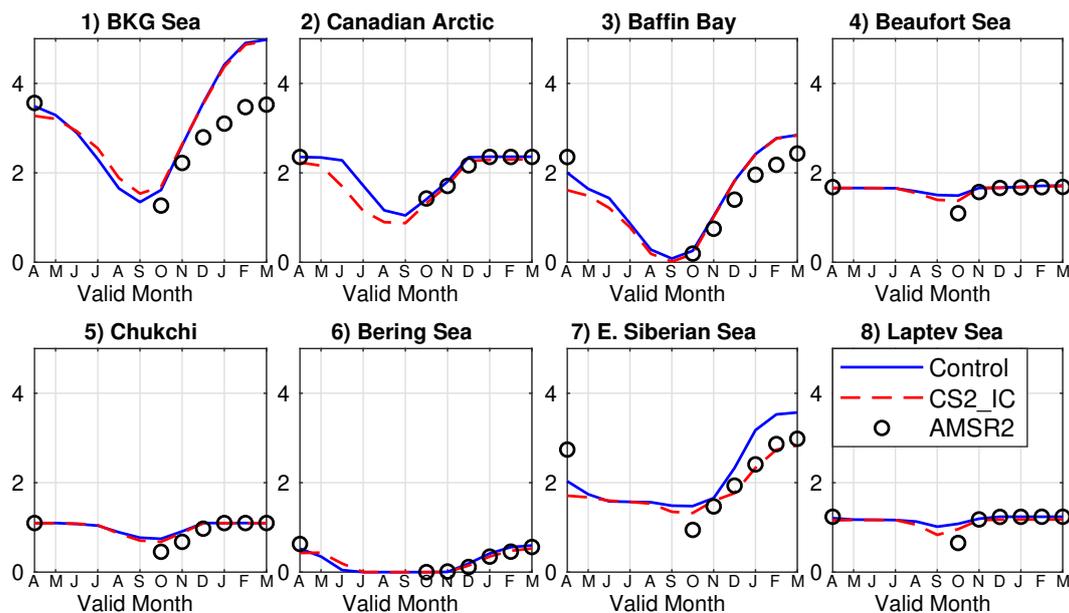

245 The experiments with both April and October initializations revealed a positive bias in SIE and SIV in the BKG Seas and Baffin Bay. This bias was attributed to inadequate simulation of the interaction between these regions and the Atlantic Ocean, primarily caused by the use of a simplified mixed layer model, as mentioned earlier. The poleward ocean heat transport from both the Atlantic and Pacific Oceans has a significant impact on Arctic sea ice, as shown in Docquier and Koenigk (2021). In the model, the absence of northward oceanic heat transport through the Barents Sea Opening, Fram Strait, Davis Strait (Atlantic
250 gateways), and Bering Strait (Pacific gateway) results in the sea ice edge extending too far south during winter.

4 Discussion

In this study, we evaluate the skill of sea ice prediction at seasonal time scales in the CICE sea ice model. The model is driven by the atmospheric forcings from the NCEP CFSR reanalysis and the built-in mixed layer ocean model in CICE. We initialize

(a) Ice Extent (10^6km^2 , IC=1 Apr 2013-2017)

(b) Ice Volume (10^3km^3 , IC=1 Apr 2013-2017)

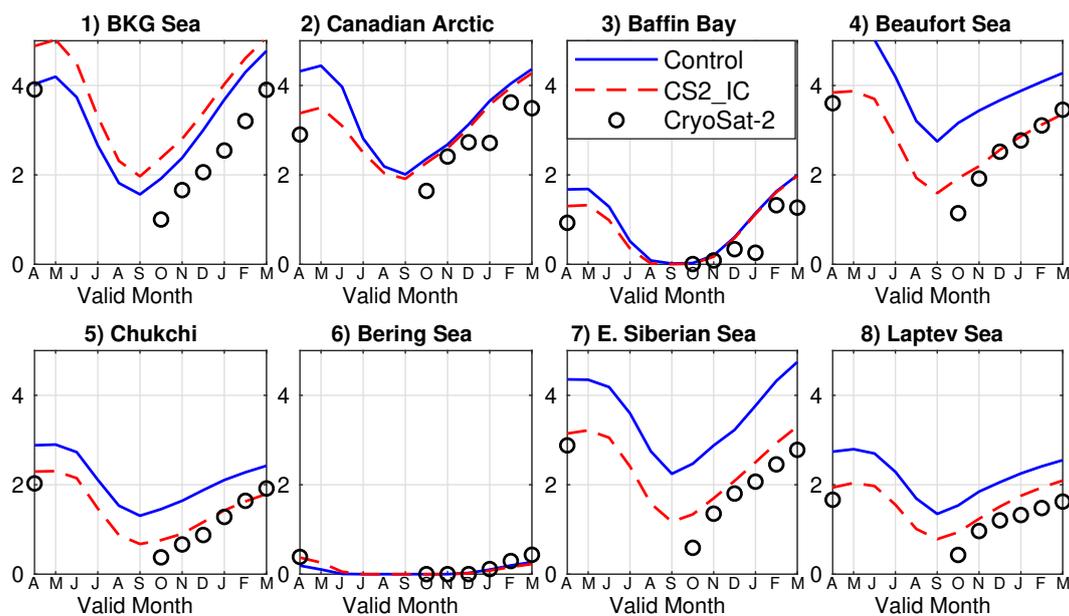

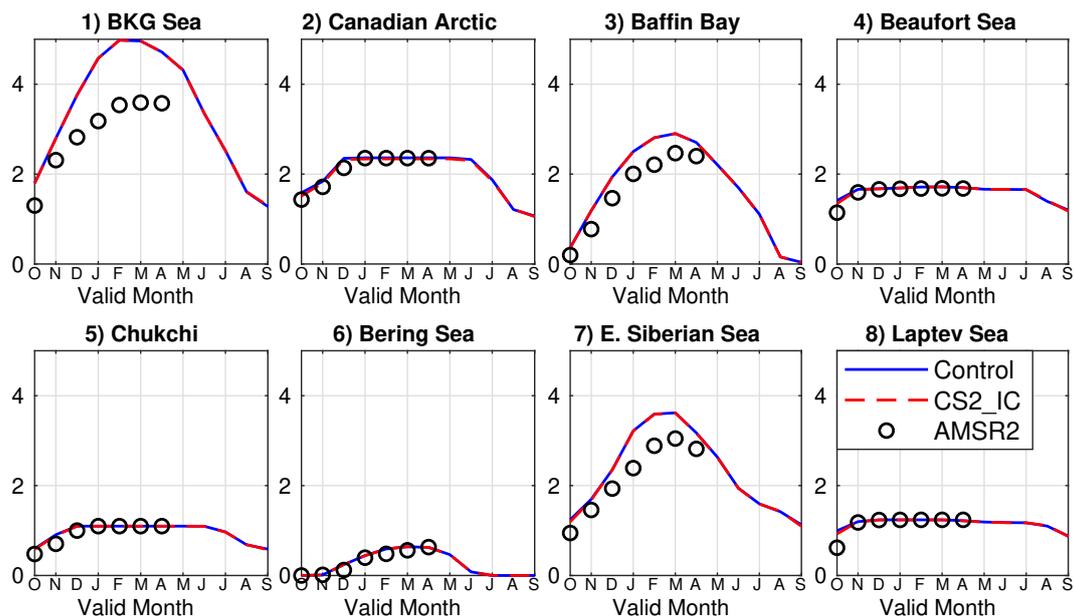

Figure 11. Sea ice extent and thickness during 12-month integration in the control (solid blue) and CS2_IC (dashed red) experiments, initialized on April 1, 2013 to 2017, as well as AMSR2 and CryoSat-2 observations (circles) in each region where (1) represents Barents, Kara and Greenland Seas (BKG) combined.

(a) Ice Extent (10^6km^2 , IC=1 Oct 2013-2017)

(b) Ice Volume (10^3km^3 , IC=1 Oct 2013-2017)

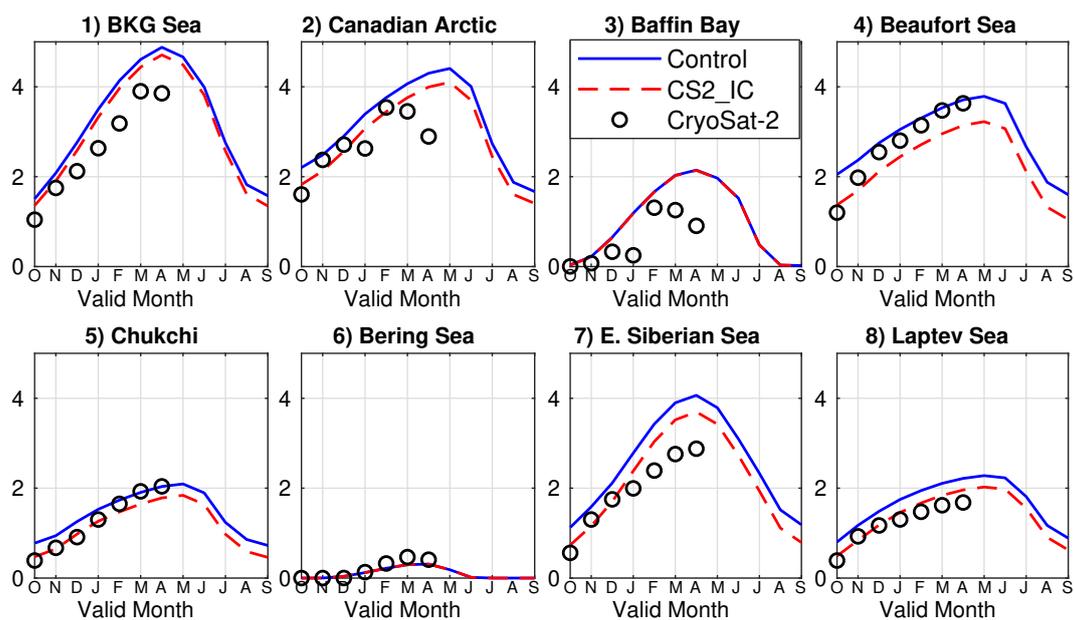

Figure 12. Same as Fig. 11, except with experiments initialized on October 1, 2013 to 2017.

the control experiments with the CFSR reanalysis for both ocean and ice states, and carry out multiple year-long experiments.
255 The model does a credible job in forecasting SIE in the warm season both in the Arctic and Antarctic at lead times up to 12 months. However, the biggest bias in the SIE seasonal forecast is in boreal late winter and early spring in the Arctic, and in austral spring in the Antarctic, which limits the seasonal prediction skill of CICE.

The biggest bias is the positive SIT in the initialization of the control experiments. The initial SIT from CFSR is consistently higher than the CryoSat-2 satellite observations, and the excessive ice thickness is often retained for more than one season. We
260 were able to reduce this bias in the CS2_IC experiments by initializing Arctic sea ice thickness using the CryoSat-2 satellite observations while keeping everything else unchanged. Although the CryoSat-2 ice thickness data are only available from October to April in the Arctic and have bias when ice thickness is low, the multi-year experiments initialized with this dataset clearly show the bias reduction in both SIE and SIV at most lead times in almost all seasons.

Once the positive SIT bias is reduced, there are still forecast biases in the CS2_IC experiments. Our analysis has uncovered
265 a cold bias in SST in the marginal ice zone, which is present in the uncoupled experimental setup that employs a simplified column mixed layer ocean model. This model neglects the northward heat transport from both Atlantic and Pacific Oceans, leading to a cooler SST. Another source of bias may be from the CFSR atmospheric forcings used to drive CICE in this study, which led to a positive SIT bias in the central Arctic. To address both issues, the next step is to incorporate CICE in a fully coupled atmosphere, ocean and sea ice system.

270 The results presented here are consistent with those in the current NOAA operational seasonal forecast model CFSv2 (Wang et al., 2013), which is the coupled model responsible for producing the atmospheric reanalysis used to force the CICE experiments in our study. However, the RMSE shown in Fig. 2 is larger than that reported in Wang et al. (2013) for a number of reasons. Firstly, the latter is based on a fully coupled model allowing feedback between atmosphere, ocean and sea ice, whereas our study uses an uncoupled sea ice model with prescribed boundary conditions which are not always 'in tune' with the sea ice
275 model. Secondly, both the ocean model and the sea ice model used in the two studies differ. Finally, the validation period also differs, with Wang et al. (2013) comparing to the 26-year climatology of 1981-2007, while the 2011-2017 period used in our study is characterized by a smaller observed sea ice area than in earlier decades.

The study brings to light that the suitability of CICE for seasonal prediction is contingent on several factors, such as initial conditions like sea ice coverage and thickness, as well as atmospheric and oceanic conditions including oceanic currents and
280 SST. These findings are consistent with previous research in the coupled climate community. Our study suggests that there is potential to improve seasonal forecasting by using a more reliable sea ice thickness initialization. Therefore, data assimilation of sea ice, ocean and atmospheric state, including sea ice thickness and SST, either from observations or reanalysis, appears to be highly relevant for advancing seasonal prediction skill.

Author contributions. SS and AS designed the study, performed the analyses and wrote the manuscript. SS carried out the numerical exper-
285 iments and did the first draft of the analyses.

Competing interests. The authors declare that they have no conflicts of interest.

Acknowledgements. This research is funded by the Global Model Test Bed at Developmental Testbed Center under NGGPS. We thank David Bailey for helpful discussions and sharing a script to convert initial conditions to restart conditions for CICE, Xingren Wu for suggesting using a mixed layer ocean instead of SST from CFSv2 and Rainer Bleck for constructive suggestions during the interval review. Discussions with
290 James Rosinski, Ola Persson, Julie Schramm, Janet Intrieri, Chris Fairall, Antonietta Capotondi and Ligia Bernardet are also much appreciated. Benjamin W. Green helped with graphics. The authors would like to express their gratitude to the three anonymous reviewers for their valuable comments, which improved the quality of this manuscript. CFSR data used here are from the Research Data Archive, managed by the Computational and Information Systems Laboratory at the National Center for Atmospheric Research in Boulder, Colorado. The ice concentration data is obtained from the National Snow and Ice Data Center (NSIDC; http://nsidc.org/data/docs/daac/nsidc0051_gsfc_seaice.gd.html).
