17 **Abstract.** Climate warming is degrading palsa peatlands across the circumpolar permafrost region. Permafrost
18 degradation may lead to ecosystem collapse and potentially strong climate feedbacks, as this ecosystem is an
19 important carbon store and can transition to being a strong greenhouse gas emitter. Landscape level
20 measurement of permafrost degradation is needed to monitor this impact of warming. Surface subsidence is a
21 useful metric of change in palsa degradation and can be monitored using InSAR satellite technology. We
22 combined InSAR data, processed using the ASPIS algorithm to monitor ground motion between 2017 and 2021,
23 with airborne optical and LiDAR data to investigate the rate of subsidence across palsa peatlands in northern
24 Sweden. We show that 55% of Sweden's eight largest palsa peatlands are currently subsiding, which can be
25 attributed to underlain permafrost landforms and their degradation. The most rapid degradation occurred in the
26 largest palsa complexes in the most northern part of the region of study, also corresponding to the areas with the
27 highest % palsa cover within the overall mapped wetland area. Further, higher degradation rates were found in
28 areas where winter precipitation has increased substantially. The roughness index calculated from a LiDAR-
29 derived DEM, used as a proxy for degradation, increases alongside subsidence rates and may be used as a
30 complementary proxy for palsa degradation. We show that combining datasets captured using remote sensing
31 enables regional-scale estimation of ongoing permafrost degradation, an important step towards estimating the
32 future impact of climate change on permafrost-dependent ecosystems.

35

36 1.0 Introduction

37 Permafrost regions are critical components in the climate system, due to their essential carbon (C) storage
38 service (Harris et al., 2022). The circumpolar permafrost region in particular, stores around 1300±200 Pg of
39 organic C, corresponding to around 50% of the global terrestrial C pool (Hugelius et al., 2020; Köchy et al.,
40 2015). It covers around 21 million km² or 22% of the Northern Hemisphere's exposed land surface (Obu, 2021).
41 Northern peatlands themselves store an estimated 415±150 Pg of C in an area covering around 3.7 million km²
42 of which around 1.7 million km² is permafrost within the circumpolar permafrost region in discontinuous and
43 sporadic permafrost zones (Hugelius et al., 2020). Permafrost in these peatlands raises the surface above the
44 water table forming so-called palsa (pl. palsas) or, in extended form, peat plateaux (Seppälä, 2011). These
45 account for substantial areas of global permafrost, including in northern Fennoscandia (Ballantyne., 2018;
46 Gisnås et al., 2017; Tarnocai et al., 2009). In northern Sweden, 137 km² of these palsa have been recorded from
47 field reports (Backe, 2014). Climate warming, and the associated alteration in the precipitation regime, is
48 increasingly recognized to be a particular threat to permafrost (Biskaborn et al., 2019), with the subarctic
49 Fennoscandian permafrost region, and the palsa within, particularly vulnerable (Christiansen et al., 2010;
50 Farbrot et al., 2013).

51 Modelling studies project unsuitable conditions for permafrost within the coming century, with the most
52 pessimistic estimates projecting unsuitability even sooner - by 2040 in Fennoscandia (Chadburn et al., 2017;
53 Fewster et al., 2022; Könönen et al., 2022; Stefan et al., 2006). As palsa are often found in the sporadic or
54 discontinuous permafrost zone (Zuidhoff & Kolstrup, 2000), they are particularly sensitive to climate warming
55 and any resultant permafrost thaw and disappearance. Their sensitivity mainly results from the alterations in the
56 thermal insulation effect of peat deposits and snow as the climate changes (Seppälä, 2011; Smith & Riseborough,
57 1996). Specifically, organic peat has a high thermal conductivity when wet and frozen, but low conductivity when
58 dry and thawed. Snow has a highly insulating effect on ground temperature. Thus, extended periods of air-
59 temperatures below 0°C and thin snow cover in winter are beneficial to maintain or grow the perennial frozen
60 core of palsas and peat plateaux. Low summer precipitation, which reduces the thermal conductivity of peat, also
61 helps to preserve the frozen cores in palsa. In contrast, increased snowfall has been linked to permafrost
62 degradation as it increases winter insulation. Further, high summer precipitation leads to higher thermal
63 conductivity of peat, and combined with warm summer temperatures, can degrade permafrost by increasing
64 permafrost temperatures and subsequent thawing of the frozen peat core of palsas. The strong insulating properties
65 of peat allow the occurrence of permafrost at the southern extent of the northern permafrost region and valley
66 bottoms in areas otherwise too warm for permafrost (Johansson et al., 2013; Seppälä, 2011; Smith & Riseborough,
67 1996).

68 Warming of the permafrost in palsa typically leads at the surface, to top-down thaw, (i.e. thickening of the
69 active layer), and eventual subsidence of the surface, as well as lateral thaw, sometimes called abrupt thaw or
70 thermokarst, which occurs at the margin of peat plateaux and palsa edges (Seppälä, 2011; Smith & Riseborough,
71 1996; Zuidhoff, 2002). This is often associated with water-logged conditions and, as a result, increased methane
72 (CH₄) emissions (Glagolev et al., 2011; Hugelius et al., 2020; Matthews et al., 1997; Miglovets et al., 2021;
73 Schuur et al., 2009; Turetsky et al., 2020; Varner et al., 2022), which is a central theme for permafrost research
74 (Sjöberg *et al.*, 2020). A subsequent impact of this permafrost degradation is an alteration in vegetation cover,
75 its hydrology, and human use of the landscape (e.g., infrastructure and reindeer husbandry)(Markkula et al.,
76 2019; Ramage et al., 2021). Given the potentially large impacts of permafrost thaw on the global climate,
77 ecosystem function and human activity, quantification and monitoring of the subsidence in peat deposits
78 affected by permafrost thaw and degradation, as well as an understanding of their sensitivity to changing
79 climatic parameters, is urgently required (IPCC, 2021).

80 The degradation of the permafrost of palsas has been observed right across the circumpolar permafrost region in
81 a number of studies, including in northern Scandinavia (Åkerman & Johansson, 2008; de la Barreda-Bautista et
82 al., 2022; Luoto & Seppälä, 2003; Olvmo et al., 2020; Sannel et al., 2016; Varner et al., 2022); Russia (Glagolev
83 et al., 2011; Miglovets et al., 2021; van Huissteden et al., 2021); the USA (Douglas et al., 2021; Douglas et al.,

84 2015; Sannel, 2020) and Canada (Mamet et al., 2017; Sannel & Kuhry, 2011; Short et al., 2014; Vallée &
85 Payette, 2007). Although rapid degradation in response to short term climatic events has been observed,
86 typically permafrost degradation has been investigated via long-term monitoring at decadal timescales in
87 response to changes in temperature and precipitation conditions (Åkerman & Johansson, 2008; de la Barreda-
88 Bautista et al., 2022; Olvmo et al., 2020; Sannel et al., 2016). These longer-term studies have shown strong
89 relationships between permafrost degradation and summer temperatures, length of the thaw period, winter
90 precipitation and snow depth (Smith et al., 2022). These types of analyses are very useful for quantifying how
91 much of the landscape has already transitioned and understanding the climate change drivers behind these
92 changes, but they do not capture the initial stages of permafrost degradation in palsas and the lower rates of
93 subsidence that have yet to result in observable changes in the vegetation or thermokarst formation. The latter is
94 crucial to understand the ongoing response of palsas to climate warming and to predict when pulses of
95 greenhouse gases to the atmosphere and other impacts (e.g., on infrastructure) are likely to occur. Thus, we need
96 approaches that detect early signs of degradation at landscape scales, with repeated observations.

97 Due to the vast extent and remoteness of permafrost areas there is no current complete annual degradation rate
98 measurements. So, we looked to satellite remote sensing to underpin the measurement and monitoring
99 assessment of permafrost peatlands, their degradation and resultant climate impacts (Hugelius et al., 2020;
100 Swingedouw et al., 2020). Optical remote sensing approaches can be augmented with RaDAR remote sensing
101 methods, including InSAR, to capture the early response of permafrost to warming. These methods can detect
102 vertical land surface motion at millimetre precision across a range of natural landscapes, with greater confidence
103 in the direction of surface motion than the absolute magnitude (Alshammari et al., 2020; Alshammari et al.,
104 2018; Bartsch *et al.*, 2016; de la Barreda-Bautista et al., 2022; Short et al., 2014; van Huissteden et al., 2021).
105 The regular sampling frequency, insensitivity to cloud and, in the case of Sentinel-1, low cost, means InSAR
106 from Sentinel-1 should be well suited to measure and monitor ongoing changes in permafrost affected by
107 climate change. Further, Sentinel-1 for InSAR is effective at both local and regional scales - the 20m × 20m
108 spatial resolution enables measurement of surface motion within local sites (de la Barreda-Bautista et al., 2022),
109 and can do so over entire and complex landscapes, such as the circumpolar permafrost region (Reinosch et al.,
110 2020).

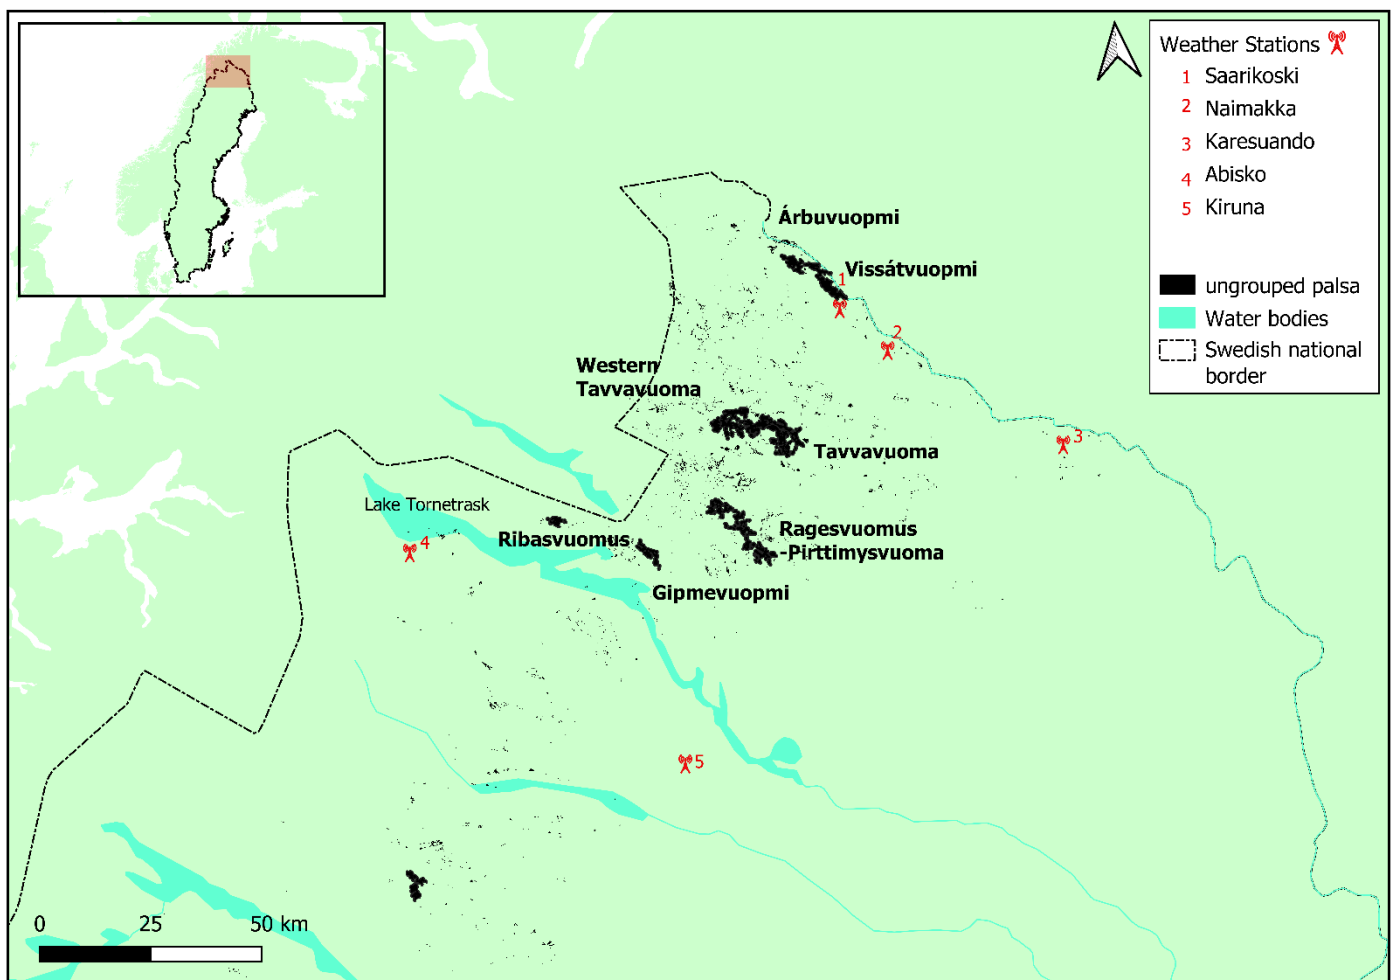

111 The overall aim of this study was to carry out a regional-scale analysis of permafrost degradation across the
112 palsas of northern Sweden, principally using Sentinel-1 InSAR-derived subsidence as an indication of
113 degradation. Pertinent to this is that any InSAR-detected changes can be associated with known and delineated
114 targets in the wider landscape. Furthermore, it is also important to understand any within-site dynamics of
115 permafrost degradation. This paper therefore has specific objectives to: (i) measure the subsidence rate between
116 2017-2021 of all major palsa complexes in the northern Sweden region; (ii) determine in which palsa complexes
117 subsidence is greatest, and (iii) assess if the spatial patterns of degradation can be linked to climatic variables
118 and properties of the different sites across the region. To achieve these objectives, we combined large-scale
119 regional analysis with higher resolution site-specific analysis of patterns in subsidence, using a combination of
120 datasets - satellite (Sentinel-1) InSAR; occupied airborne optical and LiDAR data; and snow depth,
121 precipitation, and temperature time-series from meteorological stations across the region.

122 **2.0 Methodology**

123 **2.1 Study area**

124 This study focused on the northern part of Sweden; a region containing palsa, located between 68.84-67.64° N
125 and 18.71-21.19° E. The palsas of the region are confined predominantly to valley bottoms in an elevation range
126 between ca. 350 and 590m asl (Fig. 1). The rest of the study area region is comprised of forests and/or mountain
127 land covers (Siewert, 2018; Åkerman & Johansson, 2008). Of all the palsas in the region, the eight largest
128 complexes of concentrated palsa range between 50 and 273ha in area (Table 1). These were located across the
129 region, which covers a ca. 20,000km² area, with the largest palsa sites located north-west. Smaller palsas occur
130 scattered in distribution right across the region. The climate varies from north to south (www.smhi.se). The
131 mean January and July temperatures in Karesuando in the northern part is -16 and 12.8°C, respectively, while in
132 Kiruna, slightly further south, the mean January, and July temperatures is -11.6 and 13.4C (1991-2020 average).
133 Mean annual precipitation is 443 and 560mm in Karesuando and Kiruna, respectively.

134

135 *Figure. 1: Map of the palsa in Sweden which were investigated in the study focusing on the eight named palsa*
136 *complexes. The black regions show all the palsa which has been reported to exist (Backe, 2014,) with the larger*
137 *named areas displaying the 250m buffers around the palsa areas which have created continuous expanses.*
138 *Meteorological station positions used in the study are also indicated.*

139 A previous national palsa mapping dataset provided raster cells at a spatial resolution of 100m, with the % palsa
140 cover computed and a 250m buffered output to provide continuous palsa area outputs (Backe, 2014). This
141 afforded analyses at a spatial resolution suitable for analysis with Sentinel-1 yet provide practical representation
142 of the condition of the palsa in this region. All these data were analysed in this study, but the eight largest

143 continuous areas of these palsa (Backe, 2014) were focused on, hereon in referred to as palsa complexes, a term
 144 reflecting their mosaic nature of raised palsa and/or peatland plateaux, interspersed with lower lying fen or
 145 thermokarst areas. These eight sites account for the majority of the palsa areas in Sweden, the sites are listed in
 146 Table 1 along with some associated information on their status and total and raised palsa plateaux areas.

147

148 *Table 1: Information on the major palsa complexes analysed in this paper (Backe, 2014). The protection status*
 149 *means no or limited direct anthropogenic activities that may influence palsa degradation. Total site area is*
 150 *calculated from the total number of 100m × 100m palsa pixels at each site - these pixels have associated*
 151 *percentages for how much of the 100m x 100m area is palsa. The average of these percentages for each site*
 152 *displays the palsa density at each site. These percentages are then used to calculate the “total palsa area” for*
 153 *each site based on the original report estimates.*

Site Name	Protection Classification	Total site area (ha)	Average extent palsa in these areas (%)	Total palsa area (ha)	LiDAR Collection year	Central location (Latitude, Longitude)

154

155 2.2 Datasets

156 The InSAR-derived dataset of surface motion over this northern Sweden region of study was calculated for the
 157 period between 2017 to 2021, from single look complex (SLC) C-band SAR data, captured in Interferometric
 158 Wide (IW) Swath mode by the Sentinel-1 constellation (European Union’s Copernicus Programme; Torres et al.,
 159 2012). SAR data input were from the thaw season when there was minimal coverage of snow and ice (i.e., between
 160 April and October in each year). Data from descending tracks 168 and 66 were used to cover the target area. Four
 161 stacks were processed independently with one from track 168 and three from track 66, which was split into a
 162 northern, middle, and southern subsets. The APSIS (formerly ISBAS) method (Sowter et al., 2013; Sowter et al.,
 163 2016) was used to characterize surface motion which relaxes the need for consistent phase stability and therefore
 164 enables near-complete spatial and temporal coverage over vegetated surfaces (Alshammari et al., 2020;
 165 Alshammari et al., 2018; Bradley et al., 2022; Cigna & Sowter, 2017; Gee et al., 2017; Sowter et al., 2016),
 166 including those found across snow-free permafrost regions.

167 InSAR processing of Sentinel-1 IW SLC imagery involves a series of steps summarised in Figure 2. Firstly,
 168 deburst and merging involved combining individual sub-swaths into a single wide-area SLC product. Secondly,
 169 the process of deramping produced a product where the problem of an ambiguous and rapidly changing phase
 170 with azimuth was solved for; a specific deramping function is available for Sentinel-1 data (ESA, 2015). Next
 171 step involved the co-registration of each Sentinel-1 image to a common slant range coordinate system and multi-

172 looking of data by factors of 5 m in range and 20 m by azimuth. This produced a dataset with an approximate
 173 spatial resolution of $20\text{m} \times 20\text{m}$. Using a perpendicular baseline of 250m and maximum temporal baseline of 183
 174 days \sim 2100 interferograms were generated per stack. The temporal baseline was chosen to balance the need to
 175 reduce the baseline to minimise phase ambiguities and best maintain coherence across the region, whilst also using
 176 a baseline long enough to generate season-to-season pairs over consecutive years. This is required over permafrost
 177 regions to capture more subtle trends of surface motion during the thaw period (de la Barrera-Bautista et al., 2022;
 178 Liu et al., 2010). The interferograms were unwrapped using a modified version of the SNAPHU algorithm (Shen
 179 et al., 2002), which converts circular phase data into a linear measure of deformation. The algorithm was modified
 180 in order to allow the ability to parallelise and to spread the calculation across multiple cores (Chen and Zebker,
 181 2002). The multi-annual average velocity was calculated for pixels which maintained a coherence greater than
 182 0.45 in a minimum of \sim 650 interferograms, with respect to stable reference points located in the town Kautekenio
 183 ($N^{\circ}69.00$, $E^{\circ}23.04$) for track 168 and Narvik ($N^{\circ}68.44$, $E^{\circ}17.42$), Kvikkjokk ($N^{\circ}66.95$, $E^{\circ}17.72$), and Rognan
 184 ($N^{\circ}67.09$) for the subsets of track 66. The line-of-sight measurements were converted to vertical surface
 185 displacement using a cosine correction and finally mosaicked into a single deformation product. Localised UAV
 186 studies at sites in Sweden have verified the ability to use InSAR as a tool to monitor permafrost degradation (de
 187 la Barrera-Bautista et al., 2022).

188

189 *Figure 2: A flowchart summarising the steps undertaken for InSAR processing using the APSIS method to create*
 190 *a surface motion product from Sentinel-1 IW SLC imagery. Boxes shaded grey represent data sets, boxes with*
 191 *dotted borders represent processing steps. Modified from Sowter et al. (2016).*

192 In order to interpret the resultant surface motion dataset produced by the ASPIS InSAR method, two sets of
193 additional data were sourced: (i) higher resolution remote sensing data and (ii) meteorological data. The former
194 included orthophotos captured of the eight target areas by occupied airborne surveys commissioned by the
195 Swedish Mapping, Cadastral and Land Registration Authority (www.lantmateriet.se; © Lantmateriet). The
196 orthophotos (Lantmateriet, 2021) have scenes covering a 5km × 5km area, at a 0.5m spatial resolution, the majority
197 were captured in 2021, although gaps were filled with imagery from 2018 for two sites. The Swedish National
198 Digital Elevation Model (DEM), was also used in this study. The DEM was derived via occupied airborne LiDAR
199 data capture between 2013 and 2018 (Table 1) processed to compute elevation at 2m spatial resolution across
200 Sweden (www.lantmateriet.se; © Lantmateriet). The orthophotos and DEM provided elevation and landscape
201 characteristics (geomorphic features) for use in this study. The meteorological data was captured by the Swedish
202 Metrological and Hydrological Institute (www.smhi.se) at meteorological stations across the region. Specifically,
203 the air temperature, precipitation, and snow depth data, were sourced and used from specific stations, i.e., those
204 located closest to the palsa complexes under investigation namely at Abisko, Kiruna, Karesuando, Saarikoski, and
205 Naimakka (Fig. 1).

206

207 **2.3 Data analyses**

208 2.3.1 Surface motion statistics

209 The ASPIS InSAR surface motion dataset was clipped to the 100m x 100m spatial resolution of the whole palsa
210 dataset and separately to the eight palsa complexes (Backe, 2014). From this the frequency distributions of ASPIS
211 InSAR surface motion at these eight palsa complexes, and over all individual palsa peatland raster cells in the
212 region, were produced. Using these data, the maximum and minimum rates of surface motion at each site was
213 determined, as well as the sum of the pixels with palsas that showed subsidence. These derived data relating to
214 surface motion were further interpreted using the orthophotos and DEMs, supported by the meteorological data.

215 2.3.2 Roughness thresholds

216 The DEM tiles were joined together and clipped to the eight palsa complexes. Following this, the degree of
217 elevation roughness was calculated, via the native topographic roughness index function (Riley, DeGloria, &
218 Elliot, 1999). This roughness index was thresholded at > 0.5 to provide a visual depiction of palsa landform edges
219 in the otherwise typically even terrain of the valley bottoms where the palsas occur. The roughness data was
220 visually compared to the orthophotos from a subset of areas to assess its potential for delineating palsas and this
221 allowed us to determine a threshold value that connected these continuous terrain variables to the specific features
222 of the palsa complexes, such as the raised mound structure of the palsa – so-called palsa mounds (Franklin, 2020).
223 Hillshade was also calculated via the native QGIS function using the default formula, which uses a lighting effect
224 to visualise the roughness of the terrain from differences in local elevation (QGIS, 2022). The roughness,
225 hillshade, and elevation outputs were overlaid on the mapped palsa tiles to provide higher resolution visual
226 interpretation.

227 2.3.3. Causes of surface motion

228 To test for the causes of surface motion palsa ASPIS InSAR surface motion was compared against roughness,
229 elevation and palsa percentage provided with the palsa raster cells (Backe, 2014). The roughness, elevation and
230 InSAR outputs were resampled to the resolution of the mapped palsa tiles (100m x 100m) to enable statistical
231 comparison. The zonal statistics tool was used to extract mean average values from the resulting roughness and
232 elevation outputs for the 100m spatial resolution mapped palsa tiles.

233 To analyse the relationships between surface motion, roughness and percent palsa in each 100m by 100m pixel
234 stratified by palsa complex, SciPy statistics (Virtanen et al., 2020) was used to obtain Pearson's correlation
235 statistics with an alpha value of 0.05 used to test for significance. Pandas (McKinney, 2011) and NumPy (Harris
236 et al., 2020) were used for data management. All scripts are available on the project GitHub
237 (https://github.com/SamValman/Permafrost_Sweden).

238 2.3.4 Climatic factors

239 Mean annual, maximum, and minimum daily air temperature, precipitation, and depth of ground snow for the
 240 period 2000 to 2022 from the meteorological station nearest to a correspondent palsa complex were extracted and
 241 analysed. The Naimakka station did not record snow depth and the Saarikoski station did not record air
 242 temperature, however, it was deemed that at the regional scale of this study these sites were sufficiently close
 243 together (18km) to be interchangeable. Subsequently, data was averaged to provide an annual measurement of
 244 each meteorological variable for each station/palsa complex. Due to incomplete meteorological datasets, a longer-
 245 term record of the meteorological variables was not possible for all sites. However, long-term climate data
 246 (>100years) was available from three meteorological stations in the region: namely, Karesuando, Kiruna, and
 247 Abisko. This data was used to assess temporal variability in annual, winter (December, January, and February
 248 (DJF)) and summer (June, July, and August (JJA)) temperature, precipitation and snowfall since the start of
 249 records across the region. Descriptive statistics (mean, minimum, maximum and inter-quartile range) were
 250 produced to express the regional differences between these sites. Lastly, to complement the point based
 251 meteorological (both weather and climate) data, we used modelled permafrost probabilities based on climatic
 252 conditions to explore relationships between climatic conditions (Obu et al., 2018) and subsidence rates. In this
 253 context, it is worth noting that there may be a mismatch between the modelled permafrost distribution and
 254 permafrost in palsa areas as this can, in some areas, be a relic of cooler climatic conditions. We used the mean
 255 values from the roughness and InSAR data to resample to 100m spatial resolution in line with the permafrost
 256 raster cells and spatially joined the permafrost probability layer, taking the mean value where the 100m cell
 257 straddled multiple permafrost probability cells.

258 The relationship between the meteorological variables both over the last two decades at the weather stations
 259 closest to the palsa complexes and duration of the climate record at the three weather stations with the longest
 260 data series were assessed using linear regression analysis in Genstat (VNS Ltd). Assumptions of normality and
 261 homogeneity of variance of the residuals were assessed using residual plots in Genstat. Some of time series were
 262 incomplete, in these instances the analysis was conducted using the slightly shorter time series (see fig. 8).

263

264 **3.0 Results**

265 3.1 Surface motion

266 The ASPIS InSAR-derived surface motion outputs for the time-period of interest (2017-2021), ranged
 267 between -9.9 and 7.7mm yr⁻¹ across all of the palsa raster cells measured in northern Sweden, with a mean of 0.05,
 268 median of 0.2 and range of 17.7mm yr⁻¹. Focusing solely on the eight palsa complexes provided greater insight
 269 and excluded the most extreme uplift values from scattered individual palsas (Table 2). 69% of results were within
 270 MSE of changing ground motion direction.

275

276 The spatial plots of surface motion for each palsa complex displayed in Figure 3, illustrates patterns of surface
 277 motion (both subsidence and uplift and associated variance) across this northern Sweden region. This is evident
 278 both within the palsa complexes and between the complexes.

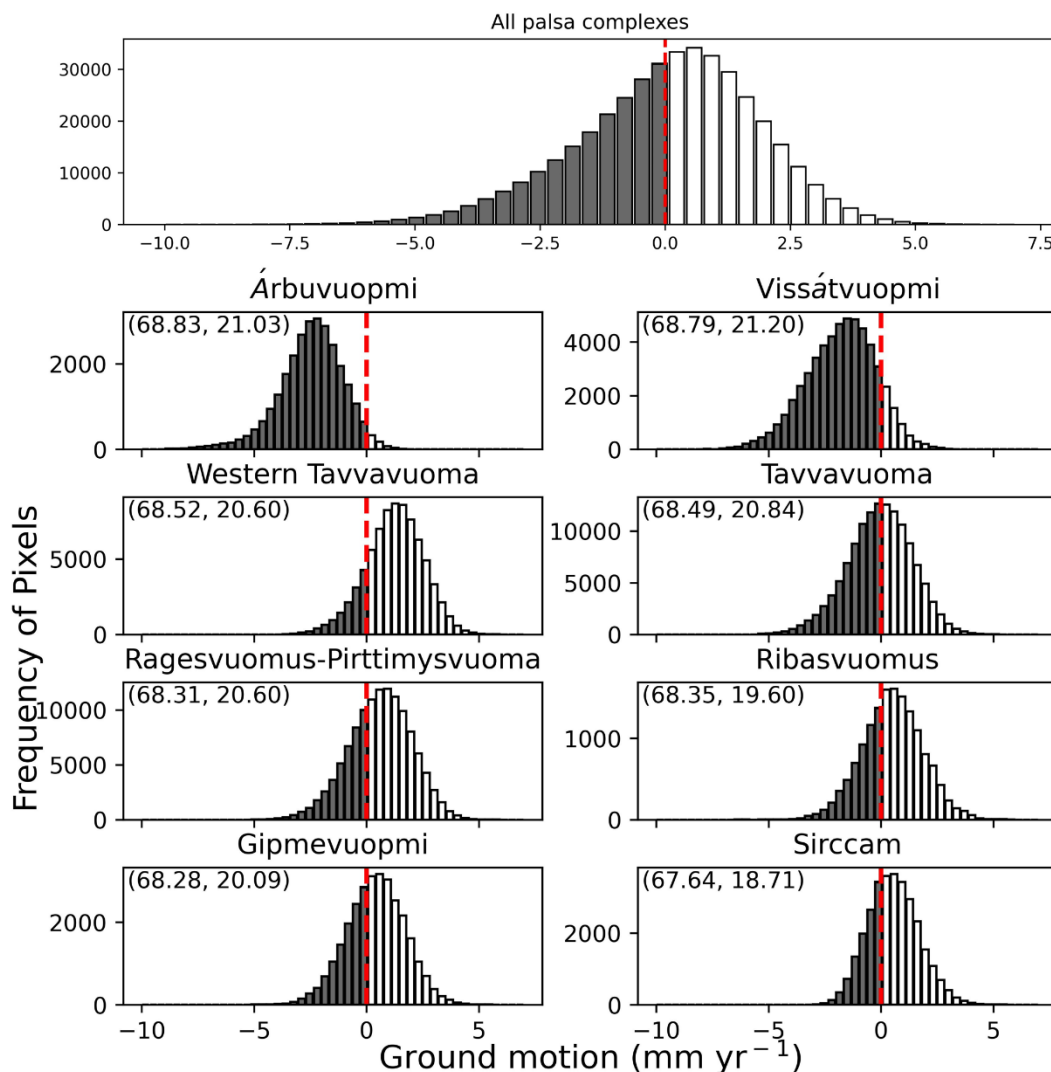

279 *Figure. 3: Palsa ground motion measured using Satellite InSAR from 2017 to 2021, showing differing levels of*
 280 *degradation across the eight study sites. Sites are ordered by their latitudinal position. Negative values*
 281 *correspond to subsidence. Note that in order to plot continuous areas the scenes shown are the palsa area plus*
 282 *a 250m buffer around each 100m × 100m raster cell that cover a minimum of 1% palsa (Backe 2014). This*
 283 *means that areas of non-palsa peatland and some areas with mineral soil are included in the figure. ASPIS*
 284 *InSAR variance were less than 1.5mm yr⁻¹ in over 90% of pixels.*

285

286 Across the target sites 3046.6ha (Table 2) out of the total site area of 5523ha (Table 1) were subsiding, which
 287 equates to ca 55% of the total palsa complexes' area. Out of the subsiding parts of the palsa complexes, 405ha
 288 were subsiding at rates $>3.5\text{mm yr}^{-1}$ at near gaussian distribution. However, it is evident from the frequency
 289 distribution plots, that it is in the palsa complexes in the far north of the region that subsidence dominated the
 290 surface motion measured (Table 2, Fig. 4). At Vissátvuompi and Árbuvuopmi 98 and 92% of the palsa complexes
 291 were subsiding with maximum subsidence rates of -9.9 and -8.9mm yr^{-1} , respectively. The measured area affected
 292 by high subsidence rates of between ($>3.5\text{mm yr}^{-1}$) were 204.8ha and 138.4ha at Vissátvuompi and Árbuvuopmi,
 293 respectively. This means that ca. 30% of the total combined area of these two sites (1194ha) is in the highest range
 294 of subsidence. The high degree of palsa subsidence at Vissátvuompi and Árbuvuopmi was confirmed by field
 295 observations at these sites (Sofie Sjogersten, pers. Obs.): Both sites showed signs of active lateral erosions, large
 296 scale subsidence and thermokarst formation. The more southerly sites also show subsidence, although ground
 297 motion rates were much more stable, with the -1 and 1mm yr^{-1} range being most common (Fig. 4). Areas further
 298 to the south and west showed signs of uplift, particularly the western parts of Tavvavuoma and Ribasvuomus with
 299 maximum rates of uplift of 6.3mm across some smaller parts of these sites. However, all sites have some degree
 300 of subsidence, albeit at a lower rate compared to the heavily subsiding northern sites.

301

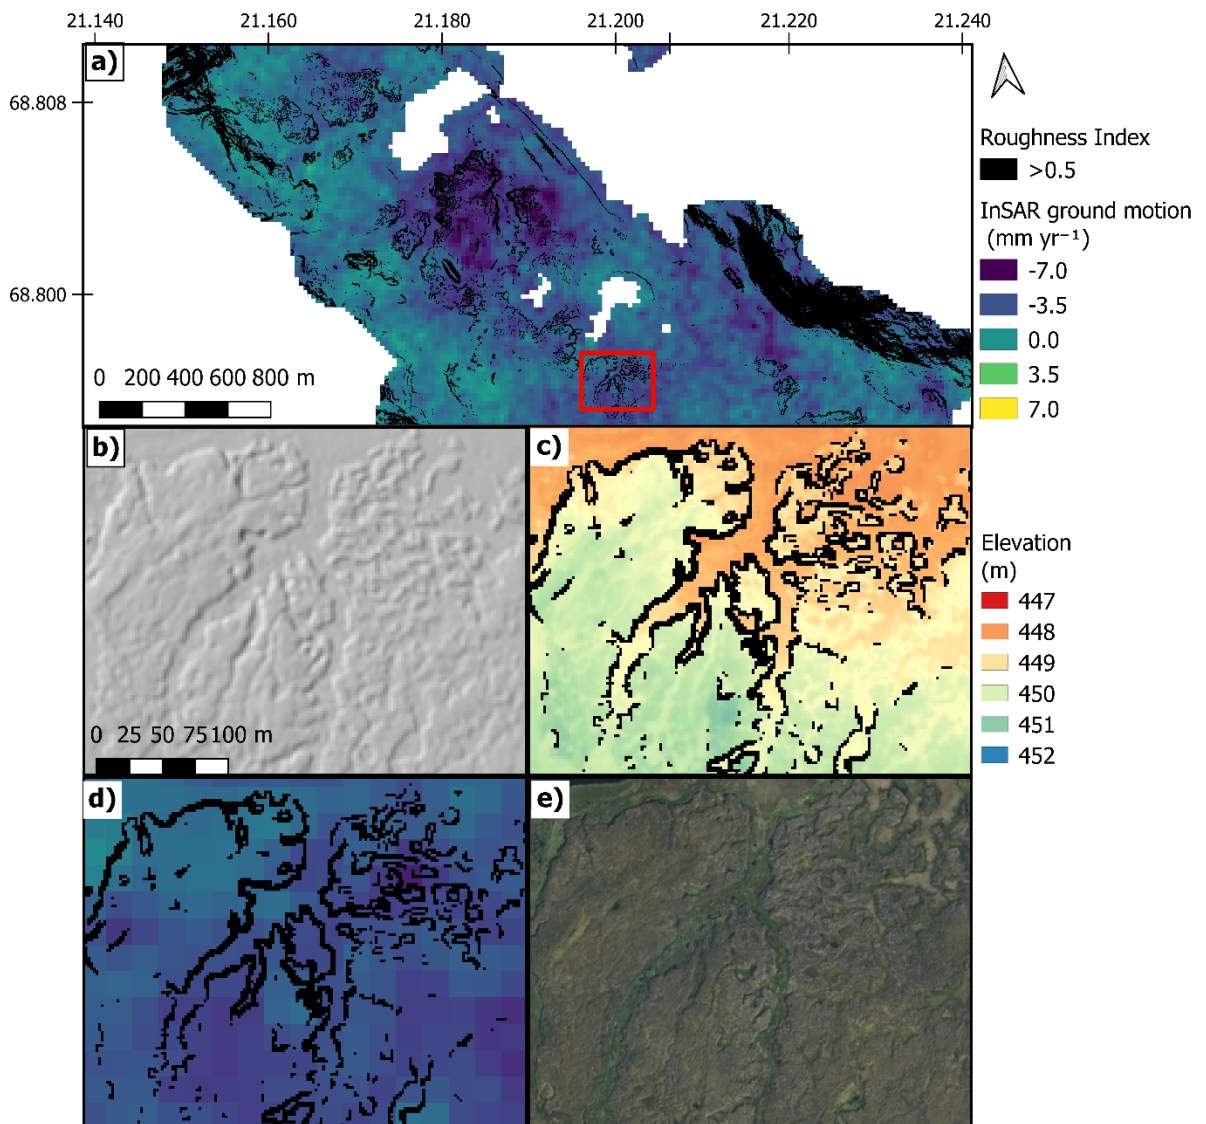

302

 305 *rate. Shaded areas with negative values correspond to subsidence. The dashed central lines indicate pixels in*
 306 *stable areas with no motion. Central point latitude and longitude is provided for each site in brackets for each*
 307 *site.*

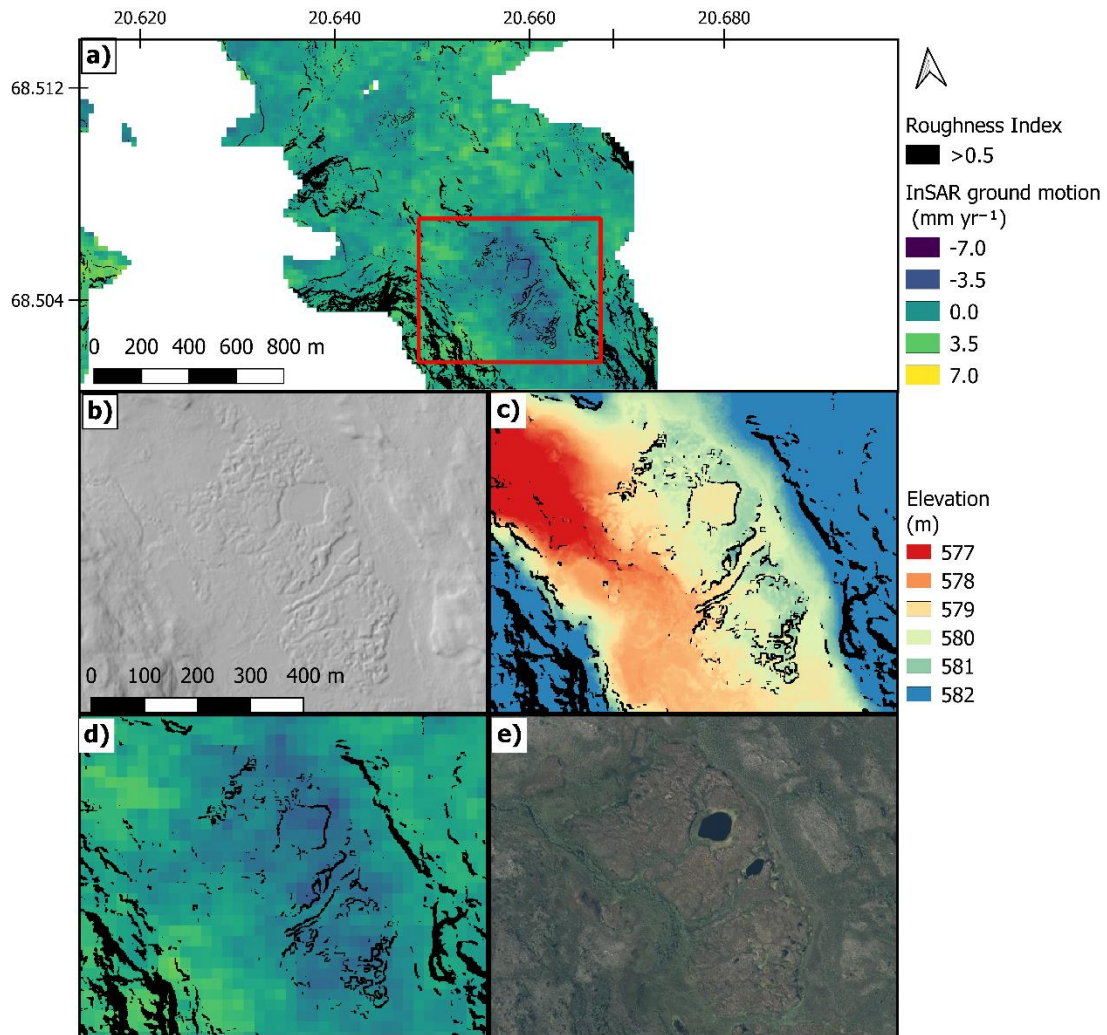

308 3.2 Topographic drivers and indicators

309 Calculating the roughness index from the DEMs at each palsa complex enabled differentiation of palsa from
 310 surrounding lower lying and flat fen areas. Representative example complexes are shown in Figures 5 and 6 -
 311 Vissátvuopmi and Western Tavvavuoma, Overall, the palsa complexes to the north (e.g., Fig. 5b, c) display a
 312 more pronounced topography across the focus areas than the more south-westerly ones (e.g., Fig. 6b, c). There
 313 was clear correspondence between density of palsa and subsidence, i.e., areas with more palsa showed more
 314 subsidence (Fig. 5a, d). Furthermore, the palsa complexes showed greater elevation variation compared to
 315 surrounding fen areas and were more densely clustered to the north than in the more south westerly sites. These
 316 features spatially coincided with higher subsidence. Substantial within site variability in subsidence was evident,
 317 where the pixels with the highest subsidence rates being clustered together and following landscapes features,
 318 e.g., palsa plateaux edges. It was evident that many separate palsa complexes in an area resulted in a high degree
 319 of elevation change, causing a high roughness index. In turn, areas with high roughness have the greatest
 320 subsidence (Fig. 5,6). Visual comparison between orthophotos and roughness showed that areas of high roughness
 321 corresponded well with areas of severe permafrost degradation (as indicated by lateral erosion and thermokarst
 322 formation).

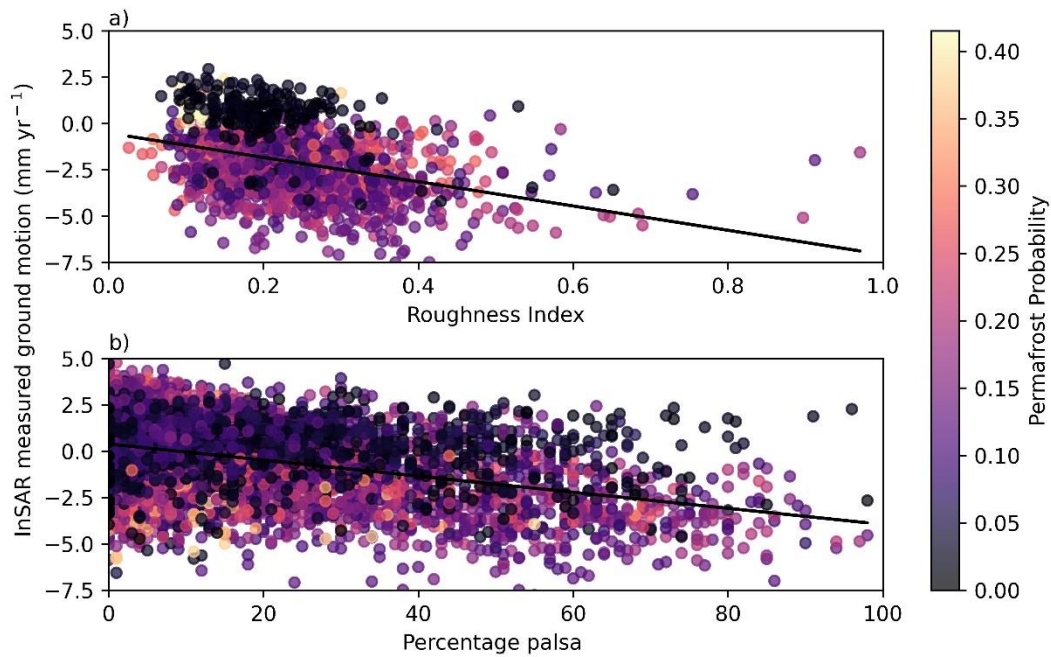

323

324 *Figure. 5: Visual analysis of Vissátvuopmi one of the sites where the most subsidence was found to be*
 325 *occurring. Evaluation of correspondence of hillshade DEM (b), DEM (c) and a close look at InSAR subsidence*
 326 *(d) with palsa complexes suggested by roughness overlays and aerial imagery (e). The positioning of b,c, and d*
 327 *within the larger site (a) show bands of subsidence proximal to roughness patches suggesting palsa.*
 328

329
 330 *Figure. 6: Visual analysis of Tavvavuoma which was found to have much lower levels of subsidence in*
 331 *comparison to more northern sites. Evaluation of correspondence of hillshade DEM (b), DEM (c) and InSAR*
 332 *subsidence (d) with Palsa complexes suggested by roughness overlays and aerial imagery (e). The positioning*
 333 *of b,c, and d within the larger site (a) show many less “bands” (linear arrangements of palsa across the image)*
 334 *of subsidence and potential palsa than Figure 4.*
 335

336 Regression analysis showed a relationship between roughness and subsidence as sites with greater subsidence
 337 were also found to have greater roughness (Fig. 7a). Higher percentage palsa in a location was linearly related to
 338 subsidence with the greatest subsidence found in areas with the highest percentage palsa cover (Fig. 7b). It was
 339 also clear that the modelled permafrost probability did not correspond to the percentage of palsa, i.e. pixels with
 340 100% palsa are in some instances predicted to have no permafrost (Fig. 7b).

341

342 *Figure. 7: Relationship between a) the roughness index; $p < 0.001$, $R^2 = 0.35$ and b) percentage palsa in a*
 343 *pixel; $p < 0.001$, $R^2 = 0.41$ and subsidence. The colours indicated for each data point are the analysed*
 344 *probability (on a scale from 0 to 1) that an area would include permafrost, (Obu et al., 2018). Note that there is*
 345 *less data for the analysis of roughness as the roughness was characterized only for the eight study sites and not*
 346 *all palsa raster cells from (Backe, 2014). Roughness values from valley sides (which at time were included in*
 347 *the buffer areas) are not used in the figure.*

348 3.4 Meteorological trends

349 The analysis of the meteorological data showed variability in both weather and climate across the study region in
 350 part reflecting the patterns in the subsidence data. The warmest minimum and maximum temperatures, -29.2 and
 351 32.8°C respectively, were recorded for the palsa complexes north of Lake Tornetrask, i.e. Gipmevuomi and
 352 Ribasvuomus (Abisko weather station) (Fig. 1). The temperature in the area of Árbuvuopmi, Vissátvuopmi, and
 353 Tavvavuoma palsa complexes (Saarikoski/Naimakka and Karesuando weather stations) ranged between -39.4 and
 354 30.5°C (Table 3, Fig. 8a). The sites had comparable annual snow depth with a mean of 20-30cm (Table 3, Fig.
 355 8b).

356

357 *Figure. 8: Mean annual a) daily maximum temperature, b) snow depth on the ground, and c) daily precipitation*
 358 *at the meteorological stations in the study region (SMHI 2022).*

359 *Table 3: Temperature and snowfall descriptive statistics. The snow depth data are estimated from days with*
 360 *snow on the ground. Mean annual temperature and precipitation are averaged from 2000 to 2021. Maximum,*
 361 *minimum and the inter-quartile range are of daily maximum temperature and daily precipitation since 2000 are*
 362 *also shown. Some weather stations lack certain years but were considered to have adequate coverage for this*
 363 *task while two sites did not have sufficient data collection during the time period to be reliable and were shaded*
 364 *out.*
 365

Weather Station	Temperature (°C)				Snow depth (m)			Precipitation (mm)		
	Mean annual	Max daily	Min daily	IQR daily	Mean annual	Max daily	IQR daily	Mean annual	Max daily	IQR daily
Naimakka	-1.40	29.5	-38.2	15.7				456	50.8	1.0
Saarikoski					76.9	0.85	0.43	422	43.6	0.9
Karesuando	-0.70	30.5	-39.4	16.9	75.1	1.00	0.40	490	53.2	1.1
Abisko	0.53	32.8	-29.2	13.5	60.0	1.27	0.42	348	61.9	0.6
Kiruna	0.06	30.3	-30.6	15.6	5.3	1.13	0.45	545	53.1	0.9

366

367

368 There was no detectable difference in climatic trends among the meteorological weather stations since 2001 for
 369 any of these sites ($p > 0.05$). In contrast, the longer-term climate records show a strong increase in winter
 370 precipitation over the last 140 years at Karesuando, the northern most weather station of the three with long term
 371 records available ($F_{1,136}=122.33$, $p < 0.001$; $\sigma^2=47.0\%$; Fig. 9a). This long-term trend was also evident, albeit less
 372 strong, in Kiruna ($F_{1,110} = 28.17$, $p < 0.001$; $\sigma^2=19.7\%$; Fig. 9b). In Abisko, the pattern of increasing in winter
 373 (DJF) precipitation was less clear ($F_{1,108}=8.29$, $p < 0.01$; $\sigma^2=6.3\%$; Fig. 9c). Mean annual Snow depth,
 374 temperature, and summer precipitation (JJA) did not show clear temporal trends (See supplementary materials).

375

377 *Figure 9. Mean winter (DJF) precipitation over time at a) Karesuando, b) Kiruna, and c) Abisko, significant*
 378 *trendlines are shown.*

379

380 4. Discussion

381 By way of satellite ASPIS InSAR-derived surface motion and associated spatial and statistical analyses, we
 382 have demonstrated on-going subsidence in the palsas of northern Sweden driven by a warming climate. Based
 383 on the compelling agreement of subsidence with palsa landforms and their roughness, we interpret this as
 384 permafrost degradation, i.e., thaw of the permafrost core within palsas and disintegration of these landforms.
 385 This is in line with a wide range of literature (see introduction) and concurs with the local-scale studies in the
 386 area undertaken using both satellite- and field-based methods (de la Barrera-Bautista et al., 2022; Olvmo et al.,
 387 2020; Sannel, 2020; Sannel et al., 2016; Sannel & Kuhry, 2011). The findings also agree with what is expected
 388 from the severe climate warming impacts on temperatures and precipitation noted in the region (Hänsel, 2020;

389 Irannezhad et al., 2017; Vikhamar-Schuler et al., 2016) and the modelled predictions of total loss of permafrost
390 across the region within decades (Fewster et al., 2022). We suggest that the surface subsidence of the sample
391 palsa complexes measured in this study, together with complementary work in Norway (Borge et al., 2017), can
392 be taken as evidence of substantial permafrost degradation in many palsa areas across northern Sweden and
393 therefore, likely to be also occurring across northern Fennoscandia

394 The processes driving the degradation of the permafrost, as measured by the ASPIS InSAR-derived subsidence
395 data, are complex. Although permafrost degradation was observed in all the palsa complexes, rates varied both
396 within and among palsa complexes (Table 2, Fig. 3 and 4). Overall, the InSAR subsidence data demonstrates a
397 south to north gradient in increasing degradation. This indicates that local factors, such as local climate warming
398 responses or permafrost temperature, determine the sensitivity of particular areas and that regional climatic
399 gradients play a role in the long-term trajectory of these ecosystems (Johansson et al., 2011; Olvmo et al., 2020).
400 In particular, winter precipitation is generally considered a strong predictor of permafrost degradation due to the
401 highly insulating properties of snow, preventing heat dissipation during winter (Olvmo et al., 2020; Seppälä,
402 2011). This points to increased winter precipitation in the part of the northern most part of study areas as a
403 driver of the higher subsidence rates at the northern most palsa complexes (Table 2 and Fig. 8a). Interestingly,
404 climate data from the last two decades did not reveal strong differences in climatic conditions over the area. This
405 suggests that long-term trends combined with a buffered system reaction to change are driving regional patterns
406 in permafrost degradation.

407 It could also be the case that the observed north to south gradient of subsidence rates reflect different phases of
408 progression in an ongoing trend of permafrost degradation across the study region of northern Sweden. It is
409 plausible that the degradation process has progressed further at the more southern sites, reflecting higher
410 permafrost temperatures, and that as a result, subsidence rates have now slowed. All the while at the northern
411 sites, which still have a high cover of palsa: 26.3 and 31.6 % at Árbuvuopmi and Vissátvuopmi respectively,
412 show high subsidence rates. This is supported by research showing rapid permafrost degradation in the
413 southernmost palsa complexes in Sweden (Zuidhoff, 2002; Zuidhoff & Kolstrup, 2000) and in the area around
414 and to the south of Tornetrask, since the 1960's (Åkerman & Johansson, 2008; de la Barreda-Bautista et al.,
415 2022; Varner et al., 2022). However, permafrost degradation in palsas have progressed over longer-time periods
416 even in northern Fennoscandia. Here palsas' have decreased in areal extent by 33– 71% over ca. 60 years, with
417 more rapid contraction in recent years in Finmarkvidda, Norway and 54% in Vissátvuopmi, northern most
418 Sweden (Borge et al., 2017; Olvmo et al., 2020) and total loss of palsa complexes has been recorded in the far
419 north eastern parts of Norway (Vorren 2017).

420 Although there are differences in subsidence rates among sites the region wide permafrost degradation reflects
421 ongoing climatic trends (Fig. 3 and 7). Since 1901 Fennoscandia's climate has become wetter as well as warmer
422 with a greater proportion of the precipitation falling as rain relatively to snow (Hänsel, 2020; Irannezhad et al.,
423 2018; Irannezhad et al., 2017; Vikhamar-Schuler et al., 2016). These trends are reflected in the far north where
424 higher air temperatures, greater precipitation and snow depths has already shifted climatic conditions, in parts of
425 the region, away from those that support permafrost in peatlands e.g. since the 1940's (Åkerman & Johansson,
426 2008; Borge et al., 2017; Olvmo et al., 2020). Further, deep permafrost boreholes show decadal signals of
427 increasing temperatures in the Scandes mountains suggesting that warmer temperatures have been impacting
428 permafrost since the 1920's (Isaksen et al., 2007). Hence, it seems that climate warming has been impacting
429 permafrost in Fennoscandia for at least 100 years.

430 As a result of the ongoing trend of increasing permafrost temperatures in palsas in Fennoscandia, their
431 permafrost temperatures are now close to 0°C, making them especially vulnerable to decay in response to
432 further increases in temperatures (Christiansen et al., 2010; Farbrot et al., 2013). Palsa formation is closely
433 linked to the mean annual temperature, with temperatures below -1 to -2°C and limited insulating snow cover
434 over consecutive years needed as a threshold for palsas to form (Vorren, 2017). In this context it is important to
435 note that the MAT in the area was between 0.53 and -1.4°C since 2000 suggesting that at least in parts of the
436 study area the climatic conditions do not support formation of palsa anymore while conditions are marginal for
437 palsa preservation in the entire region.

438 Although subsidence dominated in the northern sites, uplift was also noted in the study region. Mechanisms that
439 may explain patterns of uplift are formation of new palsa as well as short-lived frost mounds that can form
440 temporarily in the palsa system (Zuidhoff, 2002). Further mechanisms that may result in uplift are changes in
441 the water level of the flooded parts of the peatlands as well as accumulation of plant residues from the

442 productive fen vegetation parts of the study sites on the peatland surface, reflecting adaptation of the local
443 ecosystem to degraded palsa mounds reflected by changes in remotely sensed terrain surface.

444 In addition to demonstrating regional permafrost degradation in northern Fennoscandia, this work also provides
445 proof of concept for circumpolar assessments of permafrost degradation using ASPIS InSAR. It enables
446 detection of the areas with rapidly degrading permafrost and deepening active layers but also peat consolidation
447 in areas that have already lost its permafrost (de la Barrada-Bautista et al., 2022). The fact that InSAR data is
448 integrated over $20\text{m} \times 20\text{m}$ pixels means that the signal of local level degradation may be somewhat dampened
449 (de la Barrada-Bautista et al., 2022). However, the high precision of the change in vertical position means that
450 InSAR is an important tool to employ to detect the initial stages of large-scale permafrost degradation. In
451 concurrence with the literature (Alshammari et al., 2020; Alshammari et al., 2018; Bartsch *et al.*, 2016; de la
452 Barrada-Bautista et al., 2022; Short et al., 2014; van Huissteden et al., 2021), we found the majority (69%) of
453 our results were within the MSE of direction of ground motion change, providing confidence to locate where
454 permafrost is degrading. Currently, the study of long-term trends and drivers using InSAR is somewhat limited
455 by the short collection period of Sentinel 1, but as more data are continued to be collected, methods such as non-
456 linear time series creation will become viable to compare subsidence directly to longer climatic drivers.
457 However, our large-scale assessment of permafrost subsidence provides a baseline to direct, and compare,
458 against future fieldwork monitoring in northern Sweden.

459 As a complement to the ASPIS-InSAR data, the novel roughness thresholding method used here together with
460 contextual data proved a powerful tool to map and monitor changes (Franklin, 2020; Konig et al., 2019; Otto et
461 al., 2012). This approach could be developed using machine learning methods to model palsa dynamics to better
462 automate the extraction of palsa landform positions (Konig et al., 2019; Luoto & Seppälä, 2002). If
463 accomplished, the operating extent of this tool could be vastly increased using the Arctic 2m DEM dataset over
464 area where its quality is high enough to allow high resolution mapping of the degrading edges of raised palsa
465 plateaux (Morin, 2016; Karlson et al., 2021). In turn this could be used to remove the stable centre of palsa
466 plateaux and exclusively compare palsa edges to the roughness index, where we would expect to find a stronger
467 correlation than there exists with the current palsa raster cells (Fig. 7a). It has been suggested that small,
468 fragmented, and irregularly shaped palsa are more susceptible to erosion (Borge et al., 2017; Mamet et al., 2017,
469 Beer et al. in review). We have not gone as far as to estimate this here but the possible palsa edges inferred from
470 the roughness index, could be built upon for this understanding. Casual analysis of figures 5, 6 and the
471 orthophotos provided in the supplementary materials would support these expectations. Together the ASPIS-
472 InSAR and the DEM derived roughness index metrics offer novel ways of large scale monitoring of permafrost
473 degradation. This will help to quantify the rate of palsa ecosystem collapse and transition to a non-permafrost
474 state.

475 We conclude that permafrost degradation of palsas is occurring across northern Sweden, with the greatest rates
476 of degradation and largest areas impacted being Sweden's two largest palsa complexes in the far north. This
477 raises serious concerns that these systems will lose their permafrost entirely in the coming decades especially as
478 climatic conditions are approaching the limits of sustaining palsa (Fewster et al., 2022). The implications of this
479 rapid loss of permafrost is ecosystem collapse and loss, as the permafrost core is fundamental to the existence of
480 palsa. Future research should focus on the implications of this collapse on increased CH_4 emissions (Glagolev *et*
481 *al.*, 2011; Turetsky *et al.*, 2020; Varner *et al.*, 2022), carbon loss (Hugelius *et al.*, 2020), and thus the potential
482 for strong climate feedbacks (IPCC, 2021) as well as using longer-time InSAR data as this becomes available to
483 investigate regional variations in climatic drivers of permafrost degradation. Further, our study demonstrates
484 that InSAR together with terrain data can be applied over continuous natural surfaces at a regional-scale to
485 monitor permafrost degradation in palsa, offering a tool for circumpolar monitoring of climate warming impact
486 on these systems.

493 **6. Author contributions**

494 SV: Carried out the majority of the data analysis and made a significant contribution to data interpretation, writ-
495 ing and finalising the manuscript text. Both SV and MS can be considered to have contributed equally to this
496 work.

497 MS: Contributed to the conception of the study, contributed DEM and orthophoto data, carried out fieldwork to
498 assess permafrost degradation, contributed and advised on data analysis and interpretation, contributed to struc-
499 turing, writing, and refining the text. Both MS and SV can be considered to have contributed equally to this
500 work.

501 DB: Contributed to the conception of the study, advised on the data analysis, and made a significant contribution
502 to finalising the text.

503 ML: Provided data analysis, support on the InSAR processing, data interpretation, and writing of the text.

504 DG: Carried out the initial InSAR data processing

505 BBB: Contributed to the conception of the study and refining the text.

506 AS: Contributed to the conception of the study and advised on the InSAR data processing

507 SS: Conceived and directed the study, contributed to data analysis, carried out fieldwork to assess permafrost
508 degradation and made a significant contribution to formulating and finalising the text.

509 SS, DB, AS and MS secured the funding for the project.
