Abstract

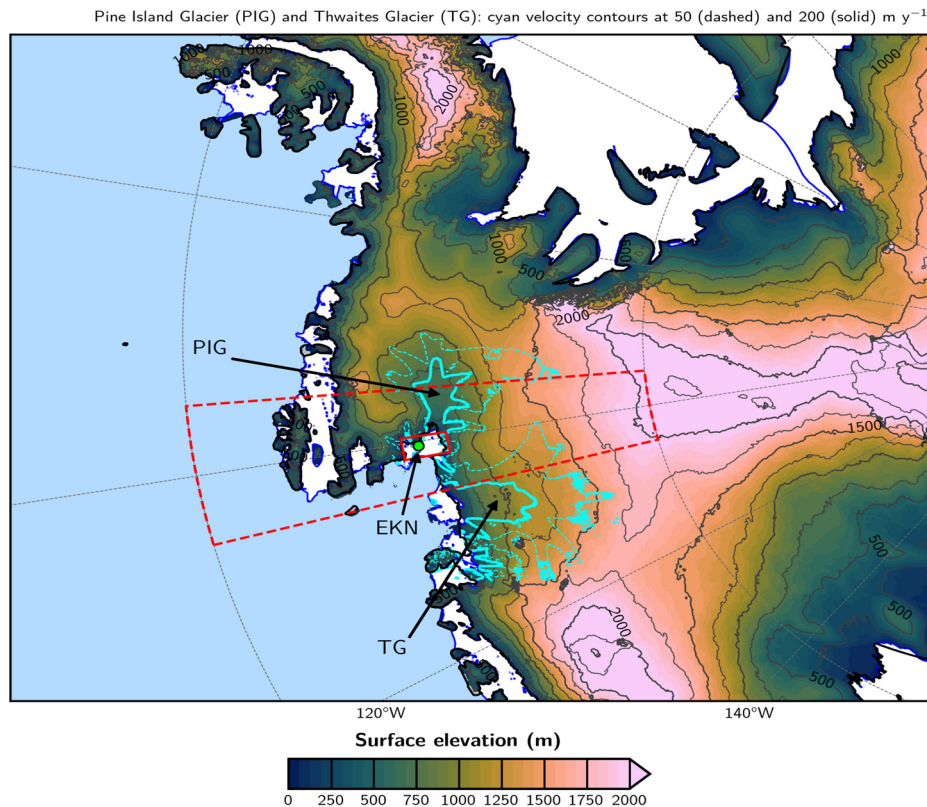

Pine Island Glacier (PIG) has recently experienced increased ice loss mostly attributed to basal melt and ocean-ice dynamics. However, atmospheric forcing also plays a role in the ice mass budget, as besides lower-latitude warm air intrusions, the steeply sloping terrain that surrounds the glacier promotes frequent Foehn winds. An investigation of 41-years of reanalysis data reveals that Foehn occurs more frequently from June to October, with Foehn episodes typically lasting about 5 to 9 h. An analysis of the surface mass balance indicated that their largest impact is on the surface sublimation, which is increased by about 1.4 mm water equivalent (w.e.) day⁻¹ with respect to no-Foehn events. Blowing snow makes roughly the same contribution as snowfall, around 0.34-0.36 mm w.e. day⁻¹, but with the opposite sign. The melting rate is three orders of magnitude smaller than the surface sublimation rate. The negative phase of the Antarctic Oscillation and the positive phase of the Southern Annular Mode promote the occurrence of Foehn at PIG. A particularly strong event took place on 09-11 November 2011, when 10-m winds speeds in excess of 20 m s⁻¹ led to downward sensible heat fluxes higher than 75 W m⁻² as they descended the mountainous terrain. Surface sublimation and blowing snow sublimation dominated the surface mass balance, with magnitudes of up to 0.13 mm w.e. hr⁻¹. Satellite data indicated an hourly surface melting area exceeding 100 km². Our results stress the importance of the atmospheric forcing on the ice mass balance at PIG.

Keywords: Pine Island Glacier, Foehn Winds, Amundsen Sea Low, Snow Sublimation, Surface Mass Balance, Ice Loss.

36 **1. Introduction**

37 The West Antarctic Ice Sheet and its marine terminating ice shelves have been thinning rapidly
38 in the last few decades, contributing to roughly 10% of the observed global mean sea-level rise
39 (Jenkins et al., 2010; Smith et al., 2020). A collapse of the West Antarctic Ice Sheet alone is
40 estimated to lead to a 3 m rise in the global sea-level (Bamber et al., 2009b), and model simulations
41 suggest it can be initiated by an ocean warming of approximately 1.2°C (Rosier et al., 2021). One
42 of the main contributors to the ice loss in West Antarctica is Pine Island Glacier (PIG), Fig. 1a,
43 which is presently Antarctica’s single largest contributor to sea-level rise (Favier et al., 2014;
44 Joughin et al., 2021; Lhermitte et al., 2021). Over the last two decades PIG has lost more than a
45 trillion tons of ice, which corresponds to a roughly 3 mm rise in sea-level (De Rydt et al., 2021).
46 Satellite images indicate a jump in the average volume loss rate around PIG from roughly 2.6 km³
47 y⁻¹ in 1995 to 10.1 km³ y⁻¹ in 2006 (Wingham et al., 2009), with recent studies stressing a further
48 speedup of ice loss since 2017 (Joughin et al., 2021; Lhermitte et al., 2021; Nilsson et al., 2022).
49 In fact, Li et al. (2022) reported a decrease in elevation around PIG, as estimated from satellite
50 measurements, at a rate of approximately -2 ± 0.04 m y⁻¹ from 2016 to 2019. Satellite data indicates
51 an ice velocity magnitude in excess of 200 m y⁻¹ over a broad region, Fig. 1a, with peak values
52 higher than 4.5 km y⁻¹ (Liu et al., 2022). The ice loss at PIG can be seen by the rapid retreat of the
53 ice front, Fig. 1b, in particular since 2015, with major calving events taking place in October-
54 November 2018 and February 2020 (Liu et al., 2022; Lhermitte et al., 2021).

Figure 1: Pine Island Glacier (PIG) and surroundings: (a) Digital elevation map (DEM) at 1 km resolution, constructed using data for March 1994-January 1995 and February 2003-March 2008, showing PIG and the Thwaites Glacier (TG). The shading and the black contours show the surface elevation (m), contoured every 500 m and labelled every 1,000m, while the regions where the ice velocity is equal to 50 m y^{-1} and 200 m y^{-1} are denoted by the dashed and solid cyan contours, respectively. The ice velocities are estimated using data from the National Snow and Ice Data Center (NSIDC; Rignot et al., 2017) for 1996-2016. The blue line highlights the ice shelves borders. The solid red rectangle represents the domain over which the averaging is performed for the time series in Fig. 7 (-101.5°W to -99.5°W ; -75.5°S to -74.5°S), whereas the dashed red rectangle highlights the domain used in Figs. 3-4 (105°W to 95°W ; 80°S to 70°S). The location of the Evans Knoll weather station (-74.85°S ; -100.404°W) is given by the green circle. (b) 19 February 2022 MODIS satellite image of PIG with an overlay of historical calving fronts since 2000.

56

57 The melting around PIG has been attributed mostly to basal melt and ocean-ice dynamics (Weber et al., 2017; De Rydt et al, 2021; Joughin et al., 2021). While ocean dynamics likely account
58 for most of the observed ice loss, atmospheric forcing may also be important in modulating PIG
59 ice loss, as it has been shown recently to be the case elsewhere in the continent (e.g. Francis et
60 al. 2021, 2022; Greene et al., 2022). Besides atmospheric rivers (Willie et al., 2021; Francis et al.,
61 2020) and associated surface radiative warming, one of the meteorological phenomena that can
62 foster ice damage around Antarctica is Foehn winds (Elvidge and Renfrew, 2016; Ghiz et al. 2021).
63 The word Foehn, which means “hair dryer” in German, refers to the warm and dry winds that
64 descend on the leeside of a mountain range. Foehn effects can trigger surface melting and snow or
65 ice sublimation (Bell et al., 2018), with melting less likely as the low humidities during Foehn
66 episodes cause large latent heat losses from the snowpack and hence prevent its warming.
67 Additionally, Foehn winds can foster calving events (Miles et al., 2017), as an offshore wind
68

69 direction, combined with ocean swells, aids in the breakup and subsequent drifting of newly
70 formed icebergs (Francis et al., 2022).

71
72 Several studies have reported the occurrence of Foehn around Antarctica such as in the Ross
73 Sea (e.g., Speirs et al., 2013; Zou et al. 2021a, b), PIG (Djoumna and Holland, 2021), Vestfold
74 Hills in East Antarctica (Gehring et al., 2022) and Antarctic Peninsula (e.g., Laffin et al., 2021).
75 Zou et al. (2021a, b) investigated the processes behind four major melting events at the Ross Ice
76 Shelf. In three of the four cases Foehn warming occurred for more than 40% of the melting period,
77 causing a 2-4°C increase in surface temperature. The authors concluded that Foehn can be an
78 important contributor to surface melting in Antarctica, which can increase the effects of warm and
79 moist air advection. Djoumna and Holland (2021) reported Foehn conditions around PIG during
80 March 2013 after the onset of a warm air intrusion associated with an atmospheric river. The
81 combination of warm and moist air advection from lower latitudes and Foehn winds likely explains
82 the record temperature of 17.5°C observed at the northern tip of the Antarctic Peninsula on 24
83 March 2015 (Bozkurt et al., 2018). A region in Antarctica particularly prone to Foehn effects is
84 the McMurdo Dry Valleys. Speirs et al. (2013) presented a 20-year climatology of Foehn events
85 at this site from weather station data. They reported positive trends for all seasons during 1999-
86 2008 with a larger magnitude in winter when the large-scale dynamics favour the occurrence of
87 Foehn. The role of Foehn winds in the disintegration and collapse of the Larsen ice shelves A, B
88 and C on the Antarctic Peninsula in 1995, 2002 and 2017 respectively, has been widely reported (
89 Massom et al., 2018). In fact, during periods of strong westerlies, the warmer and more moist
90 maritime air is forced to rise over the mountains in the western Antarctic Peninsula and warms and
91 dries out on the leeside, generating frequent Foehn events over the ice shelves on the eastern side
92 of the peninsula (Laffin et al., 2021). The complex terrain around PIG (Fig. 1a) favours Foehn
93 wind occurrence there as well.

94
95 Despite major advances in the understanding of the Antarctic surface mass balance in recent
96 decades, there are still major uncertainties (e.g. The IMBIE team, 2018) in particular in areas that
97 are prone to ice loss such as PIG (Kowalewski et al., 2021). An important process for the surface
98 mass balance is snow evaporation or sublimation (Das et al., 2013; Mottram et al., 2021), which
99 is typically difficult to detect from observations given its nature. Even though Foehn events are
100 believed to play an important role in the surface mass loss around Antarctica (Ghiz et al., 2021),
101 the underlying processes remain unclear. Moreover, no study has examined the occurrence of
102 Foehn on a longer time-scale over PIG, even though it is expected to have a significant impact
103 given the steep topography in the region (Fig. 1a). Hence, it is vital to quantify the occurrence of
104 Foehn episodes so as to better understand their role in ice loss through melting and/or sublimation.
105 This is achieved in the present work, where the occurrence of Foehn at PIG and its role in the
106 surface mass balance is investigated using a state-of-the-art reanalysis dataset, satellite imagery
107 and in situ measurements.

108

109 The remainder of the paper is organised as follows. In section 2, the datasets used in this work
110 as well as the Foehn-detection algorithm employed and how the different terms in the surface mass
111 balance are quantified are described. Section 3 provides a discussion of the occurrence and trends
112 of Foehn over PIG, as well as its impacts on the surface mass balance. In Section 4 the focus is on
113 the large-scale conditions that promote the occurrence of Foehn, while a case study in November
114 2011 is discussed in section 5. Section 6 summarises the main findings of the study.
115

116 **2. Datasets and Methodology**

117 **2.1. Observational and Reanalysis Datasets**

118 The main dataset used in this study is the ERA-5 reanalysis data (Hersbach et al., 2020),
119 which is available on an hourly basis and on a $0.25^\circ \times 0.25^\circ$ (~27 km) grid from 1950 to present.
120 Both hourly pressure-level (Hersbach et al., 2018a) and surface (Hersbach et al., 2018b) data
121 are considered in this work for the period 1980-2020. ERA-5 is one of the best performing
122 reanalysis datasets around Antarctica in comparison with station observations as noted e.g. by
123 Gossart et al. (2019).

124 The $1 \text{ km} \times 1 \text{ km}$ dataset used for the Digital Elevation Model of Pine Island Glacier (PIG)
125 and surrounding region combines measurements collected by the European Remote Sensing
126 Satellite-1 (ERS-1) Satellite Radar Altimeter from March 1994 to January 1995, and the Ice,
127 Cloud, and land Elevation Satellite (ICESat) Geosciences Laser Altimeter System from
128 February 2003 to March 2008 (Bamber et al., 2009b). The ice velocity for PIG and Thwaites
129 Glacier is estimated from a combination of satellite interferometric and synthetic-aperture radar
130 systems, and is available at a 450 m spatial resolution from 1996 to 2016 (Rignot et al., 2016).
131 Sentinel 2 satellite data, downloaded from Copernicus website (Copernicus, 2022), is used to
132 extract the sea-ice front at PIG for 2000-2022.

133 Surface radiation fluxes from the Clouds and Earth's Radiant Energy System (CERES;
134 Doelling et al. 2013, 2016) dataset are available on an hourly basis at $1^\circ \times 1^\circ$ resolution from
135 March 2000 to present. The CERES product used here is the SYN1deg - Level 3, which is freely
136 available online (NASA/LARC/SD/ASDC, 2017), and is downloaded for the period 03-14
137 November 2011 that corresponds to the case study discussed in section 5.
138

139 10-min air temperature observations at the Evans Knoll station (-74.85°S , -100.404°W ; 188
140 m above sea-level), located just to the northeast of PIG (green circle in Fig. 1a), are freely
141 available at the Antarctic Meteorological Research Center & Automatic Weather Stations
142 Project website, Space Science and Engineering Center, University of Wisconsin-Madison
143 (Lazzara et al., 2022). This data is extracted for the case study (03-14 November 2011)
144 considered in this work.

The surface melt area, for the period 03-14 November 2011, is estimated using measurements collected by the Moderate Resolution Imaging Spectroradiometer (MODIS; Kaufman et al., 1997) on board the National Aeronautic and Space Administration’s Terra and Aqua satellites. In particular, the daily global surface reflectance Level 3 data at $0.05^\circ \times 0.05^\circ$ spatial resolution (MODIS products MOD09CMG and MYD09CMG for Terra and Aqua, respectively; Vermote 2015a,b) is downloaded, and the enhanced Normalised Difference Water Index (NDWI) defined in Moussavi et al. (2016) is estimated. The NDWI index makes use of the reflectance contrast between water and ice in the red (630-690 nm) and blue (450-510 nm) bands.

2.2. Foehn-Detection Algorithm

Foehn events at PIG are identified using a modified version of the algorithm proposed by Laffin et al. (2021), in which the authors studied Foehn episodes in the Antarctic Peninsula using ERA-5, model and observational data. A given hourly time-step is denoted as a Foehn time-step if the following three conditions hold:

$$\begin{cases} 2m \text{ Temperature} > 60^{th} \text{ Percentile} \\ 2m \text{ Relative Humidity} < 30^{th} \text{ Percentile} \\ 10m \text{ Wind Speed} > 60^{th} \text{ Percentile} \end{cases} \quad (1)$$

where the temperature, relative humidity (RH) and wind speed are extracted from ERA-5, and the algorithm is applied in a $10^\circ \times 10^\circ$ domain ($105^\circ\text{-}95^\circ\text{W}$, $80^\circ\text{-}70^\circ\text{S}$) centered on PIG. The thresholds are grid-point dependent, and while the RH and wind speed thresholds are computed over the full 40-year period (1980-2020), hourly thresholds for each month are used for the air temperature to account for the annual cycle. Laffin et al. (2021) used a threshold of 0°C for the temperature as the focus was on Foehn events that cause surface melt. However, such a threshold is hardly met at PIG (Moncada and Holland, 2019; Djoumna and Holland, 2021) given its poleward location compared to the Antarctic Peninsula ($\sim 75^\circ\text{S}$ vs. $\sim 60^\circ\text{-}70^\circ\text{S}$) and resulting reduced exposure to the warmer lower-latitude air. It is important to note, however, that a surface or air temperature above 0°C is not needed for surface melting to take place. As noted by Ghiz et al. (2021), melting can occur at surface and air temperatures below freezing provided the melt energy, given by the sum of the surface radiation, turbulent and ground heat fluxes, is positive for at least two diurnal cycles. In addition to melting, Foehn promotes snow sublimation (Kirchgaessner et al., 2021) and depletes firm air content from ice shelves, which encourages meltwater-induced hydrofracture (Bell et al., 2018). Given this, the 60th percentile of the air temperature is used as the temperature threshold instead, in line with that considered for the wind speed but taking into account the strong annual variability in the region. The threshold values range from about 2 to 12 m s^{-1} for the 10-m wind speed, 232 K to 274 K for the 2-m air temperature, and 59 to 82% for the 2-m relative humidity.

182 It is important to note that ERA-5 reanalysis data lacks the spatial resolution to properly
183 resolve smaller-scale flows, and therefore may not give a full picture of Foehn around FIG.
184 However, the findings of Laffin et al. (2021) suggest that its representation of Foehn, at least in
185 the Antarctic Peninsula, is accurate enough in particular for moderate and strong episodes to
186 justify its use here. In particular, these authors found that the reanalysis captured roughly 92%
187 of the Foehn events detected with in situ weather station data. The biases in the ERA-5 radiative
188 fluxes, which in a comparison with in situ observations at Siple Dome next to the Ross Ice Shelf
189 are as large as 100 W m^{-2} for the downward shortwave and 50 W m^{-2} for the downward longwave
190 (Ghiz et al., 2021), suggest that a Foehn identification algorithm based on the surface energy
191 budget, and using ERA-5 data, may not be optimal for Antarctica. The reanalysis performance
192 in terms of 2-m temperature, relative humidity and 10-m wind speed, the fields used in the
193 Foehn detection algorithm (1), is superior, with typical biases of 0.5-1.5°C, 5-10% and 0.5-1.5
194 ms^{-1} , respectively, as noted by Gossart et al. (2019).

195 **2.3. Surface Mass Balance**

196 Over snowy regions such as Antarctica, and following Dery and Yau (1999, 2002) and
197 Scarchilli et al. (2010), the surface mass balance can be expressed as

$$198 \quad S = P - E - M - Q_{snow} - D \quad (2)$$

199 where S is the rate of accumulation or storage of snow at the surface, P is the precipitation
200 (snowfall) rate, E is the surface evaporation rate which includes the sublimation rate (Q_{surf}),
201 M represents the surface melt and runoff rate, Q_{snow} is the blowing snow sublimation rate and
202 D is the blowing snow divergence rate. All terms are expressed as mm of water equivalent per
203 day (mm w.e. day^{-1}).

204 In ERA-5, snow is regarded as an additional layer on top of the soil layer, and is characterized
205 by a snow temperature T_{sn} , with independent and prognostic thermal and mass contents. Snow
206 melting takes place if T_{sn} exceeds the melting point (273.16 K), while snow sublimation is
207 estimated with the bulk aerodynamic formula using the wind speed and specific humidity of the
208 lowest model layer and the saturated specific humidity at T_{sn} (ECMWF, 2016). The bulk
209 aerodynamic formula, used in ERA-5, performed well in estimating the observed snow
210 sublimation over the Himalayas (Stitger et al., 2018), but has not been evaluated over
211 Antarctica. What is more, blowing snow is not accounted for in the reanalysis dataset, which is
212 problematic as during Foehn events it is known to lower the albedo and increase surface
213 compaction, and hence enhance the effects of Foehn on the snowpack (e.g. Bromwich, 1989;
214 Scarchilli et al., 2010; MacDonald et al., 2018; Datta et al., 2019; Pradhananga and Pomeroy,
215 2022). As a result, the terms Q_{surf} , D and Q_{snow} in Eq. (2) are estimated as detailed below,
216 while P and M are taken directly from the reanalysis. The ERA-5 predicted surface mass
217
218
219

220 anomaly, given by precipitation minus sublimation with the monthly mass accumulation over
 221 the period 1980-2001 removed, over the Dronning Maud Land in East Antarctica for 2006-2017
 222 compares well with that estimated from the measurements collected by the Gravity Recovery
 223 and Climate Experiment satellite (Gossart et al., 2019). In fact, ERA-5 is the best performing
 224 reanalysis product out of those considered, closely following the satellite-derived estimates,
 225 with a mean absolute error of 24 Gt yr⁻¹. This justifies the use of the reanalysis' P and M in this
 226 work. All constants are defined in Table 1.

227

228 The surface sublimation rate, Q_{surf} , included in the term E in Eq. (2), is parameterized as

$$229 \quad Q_{surf} = \rho' \frac{\rho_{air} \overline{(w'q')}}{\rho_{water}} = \rho' \frac{\rho_{air}(u_* q_*)}{\rho_{water}} \quad (3)$$

230 with

$$231 \quad u_* = \frac{\kappa U}{\ln \ln \left(\frac{z + z_0}{z_0} \right)}$$

232

$$233 \quad q_* = \frac{\kappa q_{si} (RH_{ice} - 1)}{\ln \ln \left(\frac{z + z_q}{z_q} \right)}$$

234 where u_* is the friction velocity, q_* is a humidity scale, κ is the von Karman constant, U is the
 235 wind speed at height z above the surface (taken to be 10-m), z_0 is the aerodynamic roughness
 236 length, q_{si} is the saturation mixing ratio over ice, RH_{ice} is the relative humidity with respect to
 237 ice, z_q is the roughness length for moisture over snow (taken to be the same as z_0), ρ is the air
 238 density, ρ_{water} is the density of water, and ρ' is a conversion factor from m s⁻¹ to mm day⁻¹. If
 239 $RH_{ice} > 1$, q_* becomes positive and deposition to the surface is said to occur. The term $\overline{(w'q')}$
 240 is the turbulent moisture flux at the surface, with $\rho_{air} \overline{(w'q')}$ giving the sublimation rate (van
 241 den Broeke, 1997). The rate of water equivalent lost to sublimation is obtained by dividing the
 242 sublimation rate by the density of water, as done by Montesi et al. (2004).

243

244 The blowing snow sublimation rate, Q_{snow} , is expressed as in Eq. (4) below

245

$$246 \quad Q_{snow} = \frac{a_0 + a_1 \xi + a_2 \xi^2 + a_3 \xi^3 + a_4 U_{10} + a_5 \xi U_{10} + a_6 \xi^2 U_{10} + a_7 U_{10}^2 + a_8 \xi U_{10}^2 + a_9 U_{10}^3}{U'} \quad (4)$$

247

248 with

$$249 \quad \xi = \frac{RH_{ice} - 1}{2\rho_{ice} [F_k(T) + F_d(T)]}$$

250

251

$$U' = \frac{\left(1 - \frac{U_t}{U_{10}}\right)^{2.59}}{\left(1 - \frac{6.975}{U_{10}}\right)^{2.59}}$$

252

253

$$U_t = 6.975 + 0.0033 (T_{2m} + 27.27)^2$$

254

255 where ξ is a thermodynamic term, U_{10} is the 10-m wind speed, U' is a non-dimensional factor that
 256 removes the dependence on the saltation mixing ratio, U_t is the threshold for initiation of blowing
 257 snow, T_{2m} is the 2-m temperature, ρ_{ice} is the density of ice, and $F_k(T)$ and $F_d(T)$ are the
 258 conductivity and diffusion terms associated with sublimation, both temperature dependent and
 259 extracted from Rogers and Yau (1989). While negative values of Q_{surf} indicate sublimation and
 260 positive values denote deposition, the opposite is true for Q_{snow} , with positive values implying
 261 sublimation of blowing snow is taking place.

262

263 The snow transport rate, Q_t , is a vector quantity whose magnitude is given by

264

$$Q_t = BU_{10}^C \quad (5)$$

265 with the direction obtained by projecting it onto the 10-m horizontal wind vector. The divergence
 266 term D in Eq. (2) is then obtained by

267

$$D = \frac{\rho'}{\rho_{water}} \nabla \cdot Q_t \quad (6)$$

268

Table 1: Constants used in the surface mass balance.

272 **3. Foehn Events at PIG and Impacts on Ice**

273 The statistics of Foehn events at PIG are summarized in Fig. 2. Foehn is more frequent in the
274 austral winter season, in particular from June to October, and less common in the summer albeit
275 with a considerable spread in all months (Fig. 2a). The annual cycle in the duration of Foehn events
276 is less pronounced, with monthly-mean values in the range 5 to 9 h, with August featuring both the
277 highest number (~123) and longest (~9 h) Foehn episodes. At the Antarctic Peninsula, Foehn
278 occurrence peaks in the transition seasons (Wiesenekker et al., 2018; Laffin et al., 2021) whereas
279 at the McMurdo Dry Valleys located next to the Ross Sea it is more frequent in winter (Speirs et
280 al., 2013). As Foehn events are driven by large-scale pressure gradients, the difference in the
281 timing of the peaks is likely a result of the variability in the position of the baroclinic systems. In
282 particular, and as noted by Simmonds et al. (2003), the cyclonic activity in the Ross Sea, northern
283 Antarctic Peninsula and around PIG is maximized in winter whereas in the central Antarctic
284 Peninsula it is the highest in the summer. Consistent with this, in the Amundsen and
285 Bellingshausen Seas there is a pronounced equatorward shift in the mid-latitude storm track in the
286 summer months (Dias da Silva et al., 2021), which is in line with the higher occurrence of Foehn
287 at PIG in the colder months. The Amundsen Sea Low (ASL), a semi-permanent low pressure in
288 the Amundsen-Bellingshausen Seas (60°-75°S and 170°-290°E) that exhibits the largest
289 geopotential height variability in the Southern Hemisphere, is likely to play a major role in the
290 occurrence of Foehn at PIG (McLennan and Lenaerts, 2021). Meridionally, it is at its most poleward
291 location in late winter and is shifted further equatorwards in the summer, while longitudinally it is
292 the closest to PIG in the summer months (Raphael et al., 2016). As Foehn is more likely when the
293 ASL is just to north of PIG with its clockwise circulation encouraging Foehn effects in the region,
294 as noted in section 4, the intricate annual cycle of the ASL may explain the highest Foehn
295 occurrence in late winter and why it still takes place in the summer months. In the area around
296 PIG, there are on average 3.0 Foehn days in the month of August (123 occurrences over the 41-
297 year period 1980-2020) lasting roughly 7.9 h each, whereas in January there are 0.37 Foehn days
298 per month that typically last for about 5.1 h. Wiesenekker et al. (2018) reported an average of 1.3
299 to 5.8 Foehn events per month in the Antarctic Peninsula over 1979-2016, with roughly 70-80%
300 of the events in December 2014 - December 2016 lasting less than a day. These figures are higher
301 than those at PIG shown in Fig. 2a, which is due to the fact that the Antarctic Peninsula is more
302 exposed to the mid-latitude storm track, with the higher terrain on its western side promoting Foehn
303 effects.

304

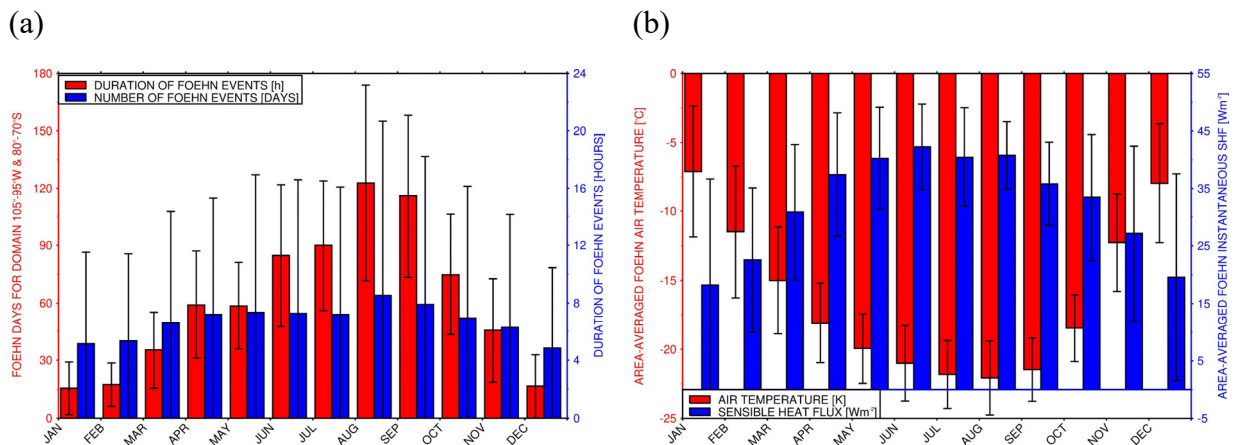

305 Fig. 2b gives the area-averaged air temperature and sensible heat flux for the Foehn events, with
306 the air temperature, sensible heat flux and RH anomalies during Foehn episodes plotted in Fig. 2c.
307 The sensible heat flux is positive, and hence directed downwards towards the surface, with
308 monthly-mean values in the range 18 to 42 W m⁻², with higher values in the winter months. This is

309 in line with Laffin et al. (2021) and with the fact that the sensible heat flux around Antarctica is
 310 maximized in the colder months when the surface to air temperature gradient is the highest, owing
 311 to the sharp thermal inversions that develop at this time of the year (Reijmer et al., 1999). The
 312 magnitude of the fluxes is comparable to that modeled over the Antarctica Peninsula (e.g. Elvidge
 313 et al., 2014) and at Joyce Glacier in McMurdo Dry Valleys (Hofsteenge et al., 2022). The air
 314 temperature during Foehn events at PIG is below freezing, ranging from -7°C in January to -22°C
 315 in August. However, melting and sublimation can still occur, in particular when accounting for the
 316 large variability which is maximized in the summer (e.g., Ghiz et al. 2021). Fig. 2c shows that
 317 Foehn effects lead to generally warmer (air temperatures anomalies typically of $+0-7^{\circ}\text{C}$) and drier
 318 (RH anomalies in the range -8% to -11%) weather conditions accompanied with a downward
 319 sensible heat flux (anomalies of $+14-21\text{ W m}^{-2}$).

320

321 Fig. 2d gives the trends in the number of Foehn days and in the duration of Foehn events for
 322 1980-2020, both of which are not statistically significant. When the analysis is extended to
 323 individual seasons, only one statistically significant trend is found, that of the duration for the
 324 autumn season, with a slope of about $-0.002\text{ days yr}^{-1}$ (not shown). Studies of trends of Foehn
 325 occurrence in Antarctica also reported non statistically significant slopes, in particular over the
 326 two major studied regions of the McMurdo Dry Valleys (e.g., Speirs et al., 2013) and the Antarctic
 327 Peninsula (e.g., Laffin et al., 2021). Fig. 2d also shows considerable inter-annual variability in both
 328 the number and duration of Foehn days. The major peaks taking place mostly in La Nina (1984,
 329 1985, 1999, 2010) or neutral (1981, 1993, 1996, 1999, 2003, 2008, 2013) years, while the
 330 minimum in 1982, 1986, 1997 and 2015 coincide with El Nino years (Lestari and Koh, 2016;
 331 Zhang et al., 2022). In La Nina conditions, the ASL is more active than normal (Raphael et al.,
 332 2016), which may promote the occurrence of Foehn, while in El Nino episodes the presence of a
 333 ridge over the Amundsen and Bellingshausen Seas (Yuan, 2004) may discourage Foehn effects at
 334 PIG. A discussion of the large-scale patterns that favor Foehn occurrence at PIG is given in section
 335 4.

336

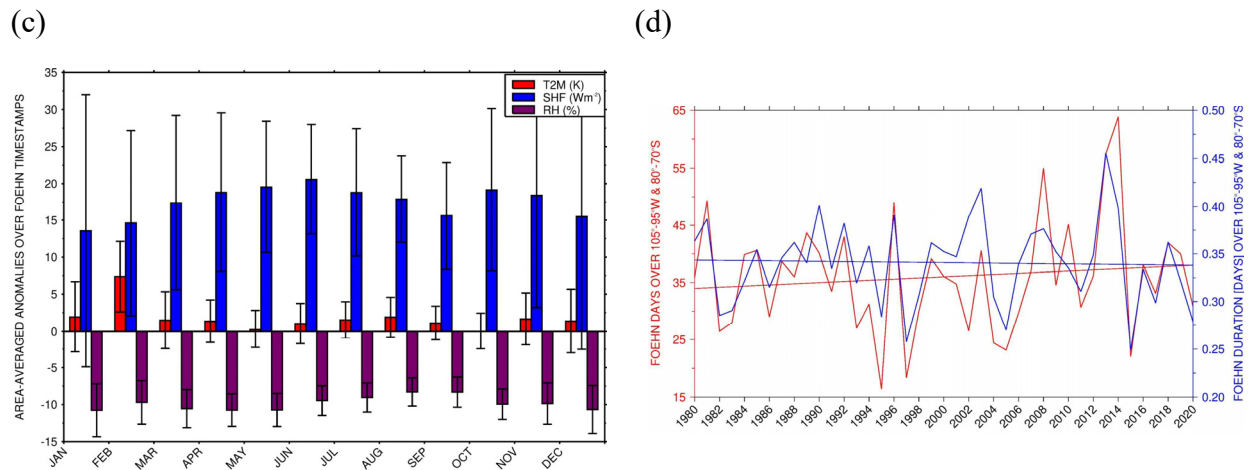

Figure 2: Climatology and trends of Foehn events: (a) Monthly mean (histogram bars) and standard deviation (error bars) of Foehn days (orange; left axis) and duration of Foehn events (hours; blue; right axis) for the period 1980-2020 and for the domain 95°W-105°W and 80°S-70°S. (b) is as (a) but for the area-averaged air temperature (°C; orange; left axis) and instantaneous sensible heat flux (W m^{-2} ; blue; right axis; positive if downwards towards the surface). (c) gives the air temperature (°C; orange), instantaneous sensible heat flux (W m^{-2} ; blue) and relative humidity (%; purple) anomalies during Foehn timestamps. (d) Trend in Foehn days (left; red) and in the duration of Foehn events (right; blue) for 1980-2020. The slopes of the Foehn days and duration are $0.101024 \text{ days yr}^{-1}$ and $-0.0001 \text{ days yr}^{-1}$ with a statistical significance of 55% and 18%, respectively.

337

338 A quantification of the potential for surface melting and sublimation is presented in Fig. 3. The
 339 “melt potential” index (MPI) is defined following Orr et al. (2022) using the daily maximum air
 340 temperature for 1980-2020, for both the full year and extended summer season (November to
 341 February, NDJF). At each grid-point, the MPI intensity is given by the difference between the 95th
 342 percentile of the daily maximum air temperature distribution for the Foehn/no-Foehn days and the
 343 melt threshold of 273.15 K, while the MPI frequency is the percentage of values higher than the
 344 threshold. The “sublimation potential” index (SPI) is defined in the same way but using the 95th
 345 percentile of the daily maximum of the hourly surface sublimation given by Eq. (3) and a threshold
 346 of zero, while its frequency expresses the percentage of the Foehn/no-Foehn days in the 1980-
 347 2020 period when there is sublimation for at least one hour per day at the site. Here, the difference
 348 between Foehn and no-Foehn timestamps is plotted for both indices to give insight into the effects
 349 of Foehn in surface melting and sublimation.

350

351 Surface melting is less common at PIG during Foehn events, with a MPI intensity and frequency
 352 reductions of about -1.3 K and -3%, respectively, with comparable values in NDJF (-0.9 K and -
 353 6%). This is expected, as the downward sensible heat flux is largely offset by the upward latent
 354 heat flux that arises from the drier near-surface air, making it harder for the snowpack to melt.
 355 Surface melting is confined to lower elevations where the temperature is higher. Here, there is also
 356 increasing exposure to the warmer and more moist maritime air masses compared to the high
 357 terrain inland. The fact that surface melting is more frequent in the adjacent Southern Ocean in
 358 Foehn episodes may be attributed both to the increased adiabatic compression of the winds as they

359 descend towards the coastal regions, and the likely presence of a low pressure system north of the
360 site during the Foehn events, as will be discussed in section 4. When all days (Foehn and no-
361 Foehn) in 1980-2020 are considered, the MPI intensity and frequency at PIG for the full year are
362 -0.27 K and 4% , respectively, and $+0.87\text{ K}$ and 10% for NDJF (not shown). Orr et al. (2022) used
363 higher spatial resolution ($\sim 12\text{ km}$) modelling products over December-February 1979-2019 and
364 for the whole Antarctica, to obtain values at PIG of $1.3\text{-}1.7\text{ K}$ and $23.7\text{-}23.8\%$. The MPI intensity
365 and frequency difference between Foehn and no-Foehn days given in Figs. 3a-b stress the role of
366 Foehn in discouraging surface melting at and around the glacier. Figs. 3c-d are as Figs. 3a-b but
367 for the SPI. The seasonal variability is much reduced compared to that of the MPI, with an intensity
368 difference between Foehn and no-Foehn days of $+1.8\text{ mm w.e. day}^{-1}$ for the full year and $+1.6\text{ mm}$
369 w.e. day^{-1} for NDJF, and a rather small change in frequency ($<0.3\%$). When all days are taken, the
370 intensity magnitudes are of about 3.34 and $3.39\text{ mm w.e. day}^{-1}$, respectively, and a frequency of
371 occurrence around 100% (not shown). The fact that the frequency is very high indicates that the
372 daily maximum in the surface sublimation is positive nearly all the time at PIG, suggesting that
373 there is at least 1 h of sublimation every day of the year for the 41-year period at the site. This also
374 explains why there is hardly any change in frequency between Foehn and no-Foehn days. The SPI
375 intensity, on the other hand, is roughly 50% larger during Fohn episodes, highlighting the role of
376 Foehn effects in the surface sublimation. It is interesting to note that, even though the near-surface
377 wind in the region is stronger in the colder months, the effects of Foehn on the 10-m wind in NDJF
378 are largely similar to that in the full year (cf. Figs. 3c-d). The convergence of the near-surface wind
379 in the PIG basin and the lower heights and consequently higher temperatures explain the maximum
380 in surface sublimation in the region seen in Figs. 3c-d.

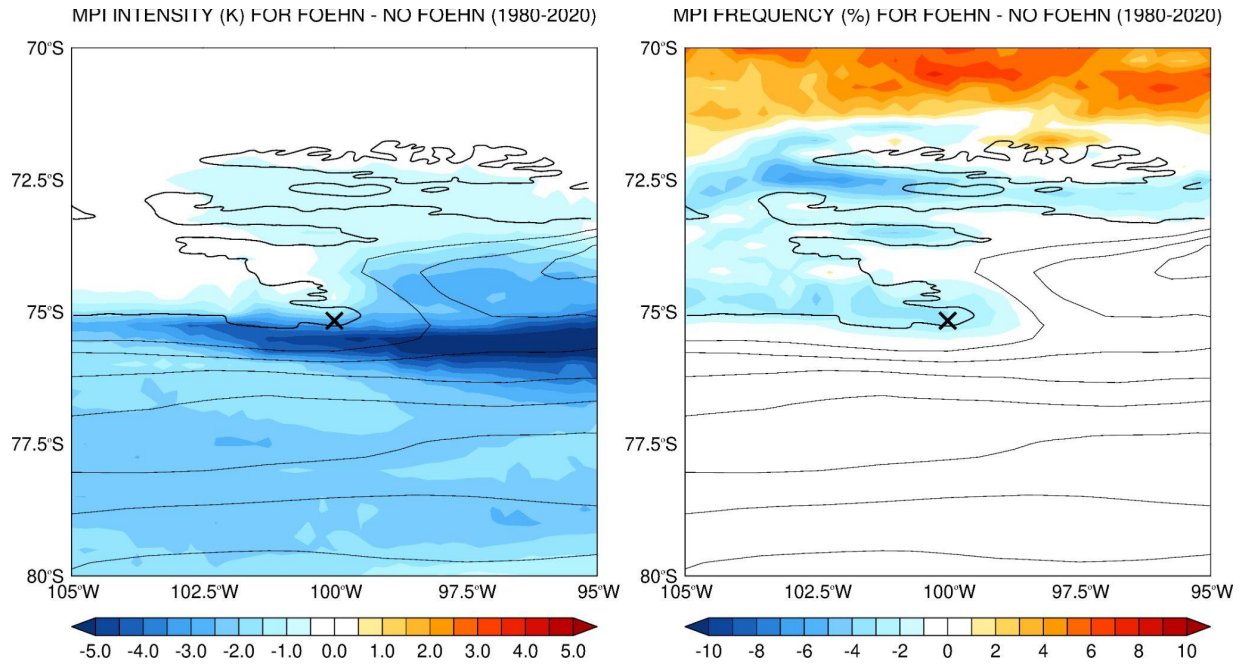

381
382 In order to explore the contribution of Foehn to the surface mass balance, Figs. 4a-f show the
383 composite difference of the terms in Eq. (2) between Foehn and no-Foehn timestamps for 1980-
384 2020. The Foehn minus no-Foehn values of the rate of accumulation or storage of snow at the
385 surface (S), precipitation (snowfall) rate (P), surface melt and runoff rate (M), surface sublimation
386 rate (Q_{surf}), blowing snow sublimation rate (Q_{snow}) and blowing snow divergence rate (D) at
387 PIG are $S \sim -1.411$, $P \sim -0.345$, $M \sim -0.005$, $Q_{surf} \sim -1.434$, $Q_{snow} \sim 0$ and $D \sim -0.363\text{ mm w.e.}$
388 day^{-1} , respectively. This indicates that (i) surface sublimation plays the dominant role in the surface
389 mass balance during Foehn events (note that negative values of the surface sublimation rate, Q_{surf} ,
390 and positive values of the blowing snow sublimation rate, Q_{snow} , indicate sublimation); (ii) the
391 sum of the two blowing snow terms, Q_{snow} and D , has a magnitude comparable to that of the
392 precipitation/snowfall, P , roughly 25% smaller than that of the surface evaporation, but with the
393 opposite sign in Eq. (2), reflecting a lack of snowfall during Foehn episodes due to the drier
394 conditions while the convergence of blowing snow at the glacier basin adds to the surface mass;
395 (iii) snow melting, M , makes a negligible contribution to the surface mass balance, being roughly
396 three orders of magnitude smaller than the surface sublimation.

397

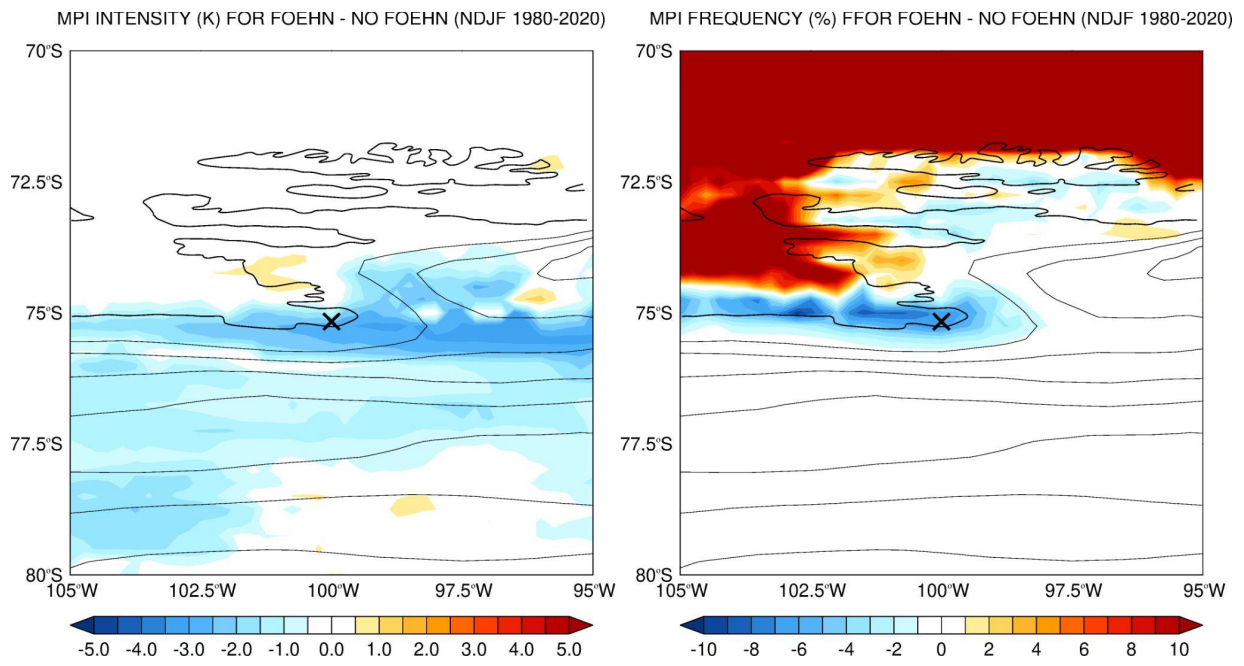

398 The surface sublimation rate (Fig. 4c) is considerable, with the values at PIG comparable to the
399 maximum rates at a site in northern Victoria Land during November 2018 (Ponti et al., 2021),
400 but roughly an order of magnitude smaller than that due to melting resulting from ice dynamics
401 around Antarctica, including at PIG (Holland et al., 2007; Rintoul et al., 2016; Feldmann et al.,
402 2019). Surface melting is negligible and confined to the coastal regions further north (Fig. 4d). As
403 noted by Scarchilli et al. (2010), and in line with our findings (Figs. 4e-f), blowing snow plays an
404 important role in the surface mass balance during strong wind (here Foehn) episodes. The
405 magnitude of the total blowing snow sublimation and transport reported in that study, which are
406 measured at the Terra Nova Bay in the Ross Sea, are larger than those estimated here at PIG. This
407 is consistent with the fact that katabatic wind events at Terra Nova Bay can be quite strong, being
408 associated with much higher wind speeds than those during the Foehn events discussed here
409 (Aulicino et al., 2018). Blowing snow sublimation (Fig. 4e) peaks just south and east of the glacier,
410 with values in the range $0.5\text{-}0.75\text{ mm w.e. day}^{-1}$, where the wind speed exceeds the threshold for
411 blowing snow sublimation, Eq. (4). The convergence of the blowing snow transport rate from the
412 east and southeast of PIG leads to the negative divergence at the basin (Fig. 4f). The negative
413 values in the snowfall rate plot to the south and north of PIG, Fig. 4b, reflect the reduced
414 precipitation in association with Foehn events. The changes in the storage term between Foehn
415 and no-Foehn timestamps, Fig. 4a, are comparable to the modelled surface mass balance in the
416 region (Donat-Magnin et al., 2021), suggesting that Foehn events are a major contributor to it.
417 Figs. 4g-h gives the differences in the 10-m wind speed and sensible heat flux. During Foehn
418 episodes, there is a strengthening of the near-surface wind by $5\text{-}10\text{ m s}^{-1}$ with it converging into
419 PIG. The sensible heat flux increases by about $30\text{-}40\text{ W m}^{-2}$, in line with the area-averaged values
420 in Fig. 2b. While in other regions of Antarctica, such as the Antarctica Peninsula, Foehn plays an
421 active role in snow melting (Laffin et al., 2021), at PIG it seems to trigger mostly sublimation.

422

(b)

(c)

(d)

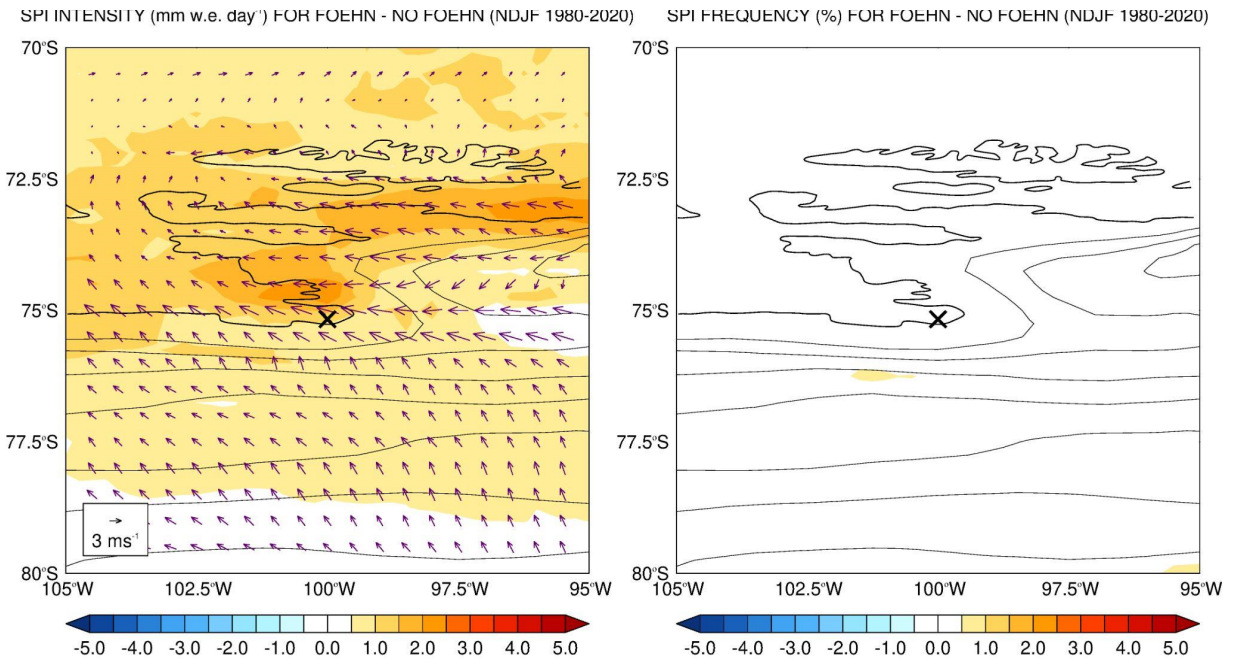

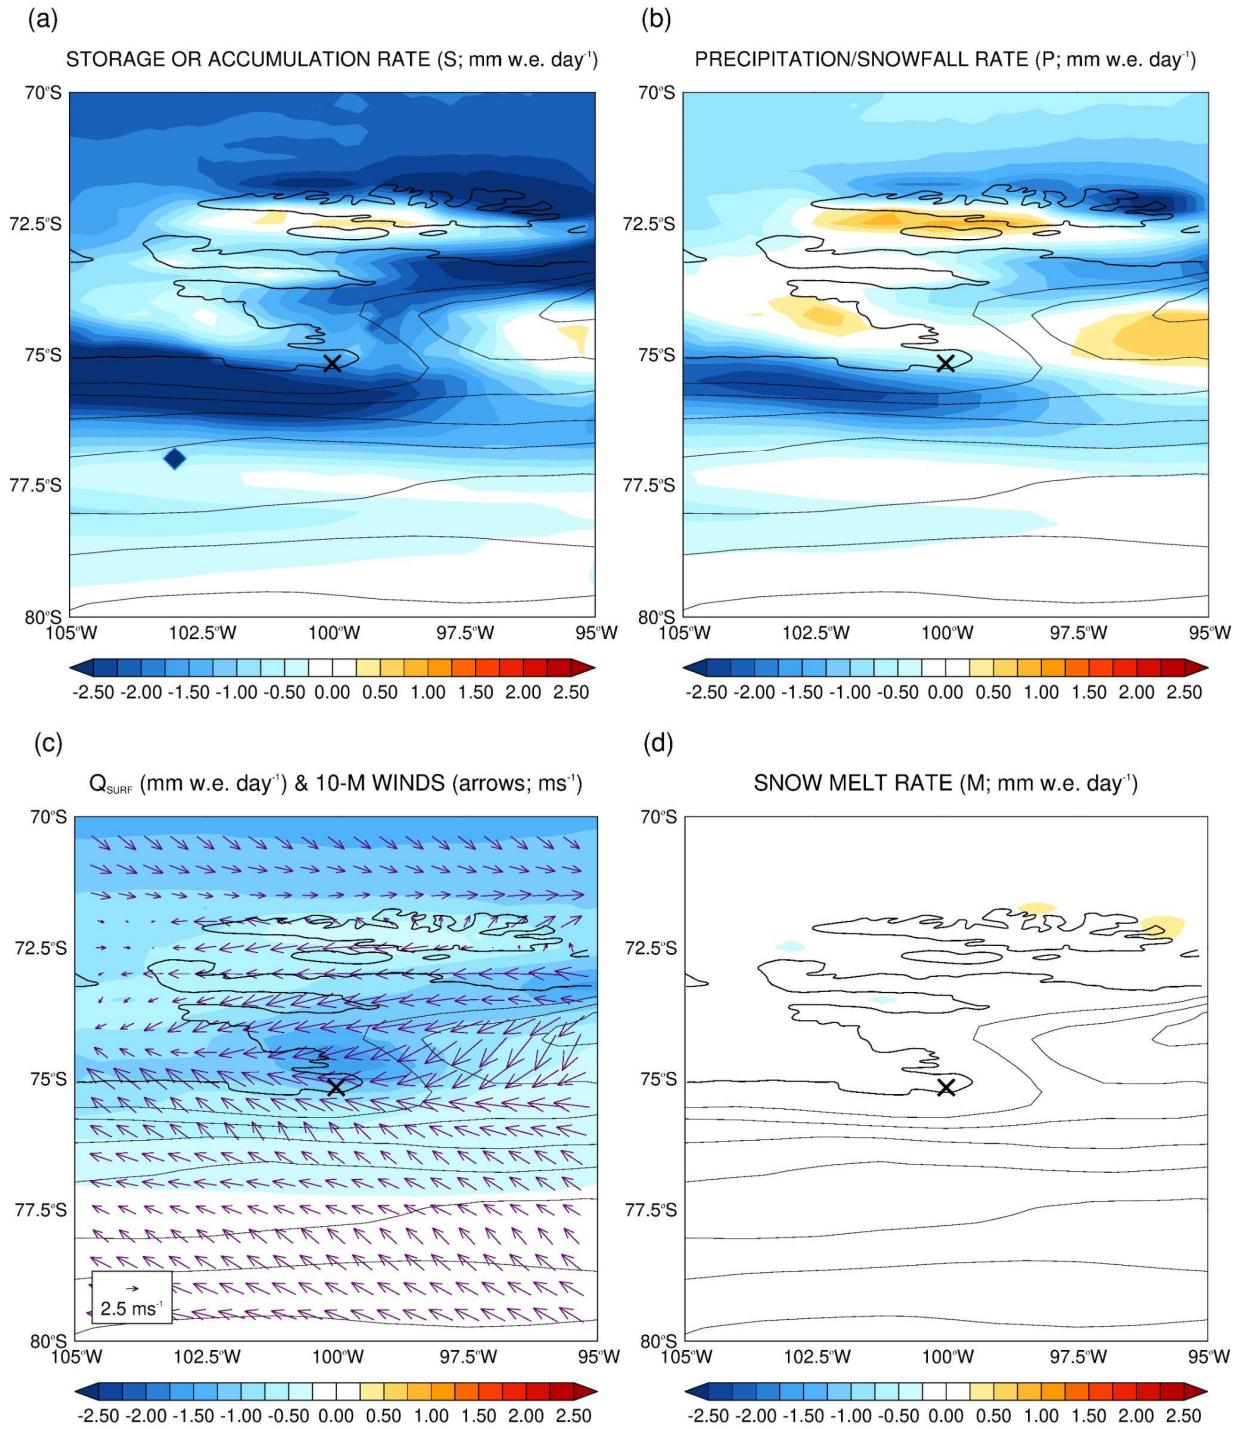

Figure 3: Melt and Sublimation Potential Indices: (a) “Melt Potential” index (MPI) intensity (K; left) and frequency (%; right), defined following Orr et al. (2022), for the difference between Foehn and no-Foehn timestamps for 1980-2020. The thin black lines are 250 m orography contours and the land-sea mask is represented by the thick black line. The cross gives PIG location (100°W, 75°10’S). (b) is as (a) but for November-February (NDJF) only. (c)-(d) are as (a)-(b) but for the “Sublimation Potential” index (SPI), with the intensity given in mm of water equivalent per day (mm w.e. day⁻¹). The averaged 10-m horizontal wind vectors are drawn as arrows in the left panels of (c)-(d) for the respective period.

COMPOSITE OF FOEHN - NO FOEHN TIME STAMPS FOR 1980-2020

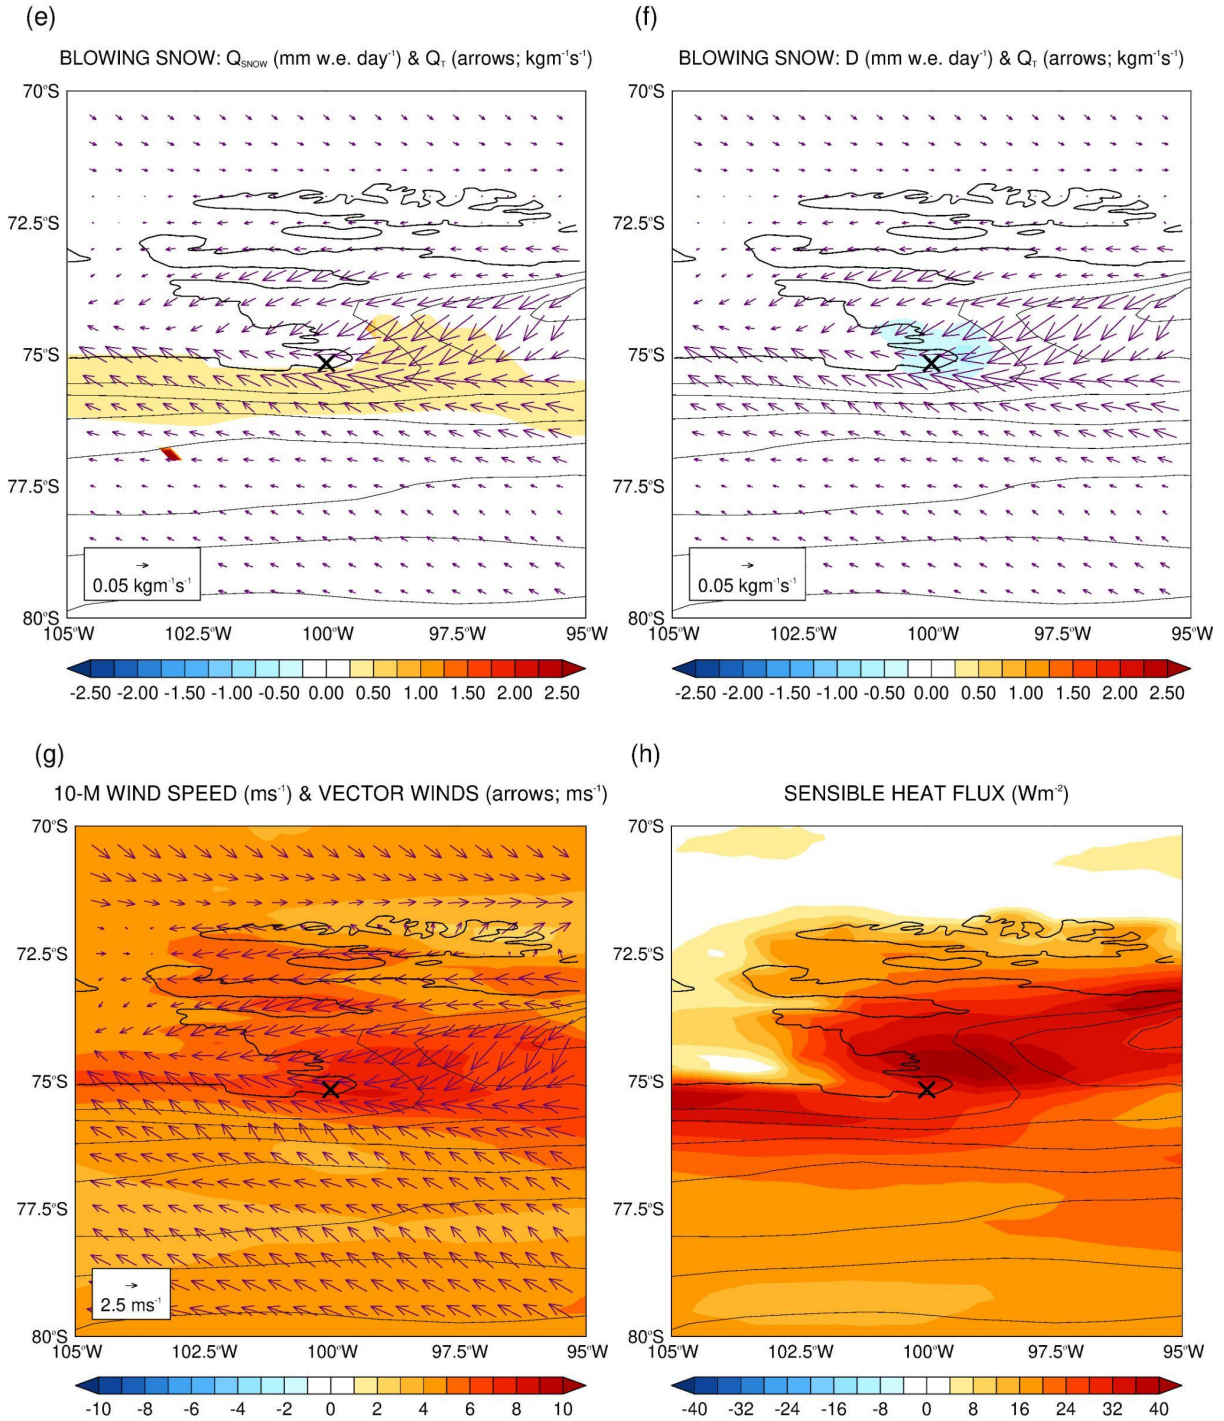

Figure 4: Composite difference between Foehn and no-Foehn timestamps for 1980-2020: (a) Storage or accumulation rate of snow at the surface (S in Eq. (2); mm w.e. day⁻¹), (b) precipitation/snowfall rate (P ; mm w.e. day⁻¹), (c) surface sublimation rate (Q_{surf} ; mm w.e. day⁻¹; positive values indicate deposition to the surface and negative values indicate sublimation), (d) snow melt rate (M ; mm w.e. day⁻¹; positive values indicate melting), blowing snow (e) sublimation rate (Q_{snow} ; mm w.e. day⁻¹; positive values indicate sublimation) and (f) divergence rate (D ; mm w.e. day⁻¹), (g) 10-m wind speed (shading; ms⁻¹) and (h) instantaneous surface sensible heat flux (W m⁻², positive if downwards towards the surface). The arrows in (c) and (g) give the 10-m horizontal wind vectors (m s⁻¹) while in (e)-(f) they show the blowing snow transport rate (Q_t ; kg m⁻¹ s⁻¹).

423 4. Large-scale Circulation Favorable for Foehn Occurrence

424 Foehn events are driven by large-scale pressure gradients, so it is of interest to investigate the
425 patterns in the atmospheric circulation which promote their occurrence around PIG. The k-means
426 clustering technique (Steinley, 2006) is applied to the daily 200 hPa and 850 hPa geopotential
427 height and wind anomalies and to the sea-level pressure and 10-m wind anomalies for the Foehn
428 days identified in 2000-2020. However, and to exclude localized events, only days when Foehn
429 occurred in at least 10% of the 105°-95°W and 70°-80°S region are considered, leaving 1181 days
430 for the analysis. A different number of clusters from one to five are tested, and the optimal number,
431 as determined by a silhouette analysis (Rousseeux, 1987), is found to be two (not shown). Cluster
432 1 (Figs. 5a-b), which features the negative phase of the Antarctic Oscillation (AAO; Gong and
433 Wang, 1999), accounts for ~58% of the total Foehn events. Cluster 2 (Figs. 5c-d), which projects
434 onto the positive phase of the Southern Annular Mode (SAM; Marshall et al., 2003), an index
435 which gives an indication of the strength and latitudinal position of the westerlies in the Southern
436 Hemisphere, accounts for ~42% of the 1181 Foehn episodes. The clusters' annual cycle is given
437 in Fig. 5e. For computational reasons the cluster analysis was not extended to 1980-2020. In any
438 case, the findings are unlikely to change should the technique be applied to the 41-year period,
439 with the AAO and SAM most certainly the dominant modes.

440
441 The first cluster (Fig. 5a) comprises a wavenumber #1 with an equatorward shift in the mid-
442 latitude storm track as evidenced by the high pressure over Antarctica and a nearly circumglobal
443 low pressure equatorwards. It corresponds to the negative phase of the AAO, with the easterly to
444 northeasterly winds around PIG promoting the occurrence of Foehn. The air mass comes from the
445 Weddell sector and moves over the Ellsworth Land before flowing down the length of PIG
446 drainage basin (Fig. 5b). The wavenumber #1 is maintained by both low-latitude forcing
447 (Quintanar and Mechoso 1995a and b) and the high topography of Antarctica (Hoskins and Karoly,
448 1981). As noted by Pohl et al. (2010), the AAO has a strong correlation with ENSO, with El Nino
449 events favoring its negative phase. This mode dominates in the colder months from May to August
450 (Fig. 5e) when the ASL is displaced westwards (Raphael et al., 2016) and hence the SAM has a
451 smaller impact on the weather conditions at PIG.

452
453 The second cluster (Fig. 5c) projects onto the positive phase of the SAM in which the storm
454 track is shifted poleward and the ASL is significantly deeper (Fogt and Marshall, 2020; Zheng and
455 Li, 2022). McLennan and Lenaerts (2021) found that the ASL modulates the total annual snowfall
456 at the Thwaites Glacier adjacent to PIG (Fig. 1a). This cluster shows the winds descending the
457 slopes immediately to the east of the Pine Island ice shelf. The air mass comes from the Pacific
458 Ocean and flows over the high terrain and coastal mountains directly to the northeast of PIG before
459 descending downslope into the glacier basin (Fig. 5d). The cyclonic (clockwise) circulation motion
460 associated with the ASL, and its interaction with the high terrain to the east of PIG, leads to Foehn
461 conditions around the glacier. Cluster #2 features a wavenumber #3 across the Southern
462 Hemisphere.

(d)

(e)

Figure 5: Large-scale conditions promoting Foehn events: (a) 200 hPa geopotential height anomalies (shading; m) and wind vectors (arrows; m s^{-1}) and (b) mean sea-level pressure (shading; hPa) and 10-m wind vectors (arrows; m s^{-1}) for cluster #1 of a k-means clustering technique applied to the daily-mean fields of 1181 Foehn days at PIG in 2000-2020. The cross gives the approximate location of PIG (100°W , $75^{\circ}10^{\circ}\text{S}$). (c)-(d) are as (a)-(b) but for cluster #2. The monthly occurrence of each cluster is given in panel (e).

464 5. Illustrative Case Study: November 2011

465 The effects of Foehn at PIG are discussed for an event in November 2011. Fig. 6 summarises
466 the large-scale environment that promoted the occurrence of Foehn, while Fig. 7 presents a time-
467 series of spatially-averaged meteorological variables that allows for a quantification of the Foehn
468 effects.

469
470 The ASL was particularly deep on 10-11 November 2011, with the 500 hPa geopotential height
471 anomalies more than 1.5σ below the 1979-2020 mean (Figs.6a-b). An atmospheric river associated
472 with an elongated and narrow band of high moisture content and integrated vapour transport (IVT)
473 values in the top 10% of the climatological distribution, extended from the Southern Hemisphere
474 mid-latitudes into West Antarctica and PIG, being transported by the clockwise circulation of the
475 ASL. As the ASL edged closer to the Antarctica Peninsula on 11 November (Fig. 6b), the more
476 moist air, now over the Weddell Sea, penetrated further inland reaching PIG and the surrounding
477 region from the east (after flowing over the ice divide that separates the Weddell Sea and Ronne
478 Ice Shelf from PIG and the Amundsen Sea region). As a result, the IVT at PIG more than doubled
479 from about $27.5 \text{ kg m}^{-1} \text{ s}^{-1}$ on 10 November to around $65 \text{ kg m}^{-1} \text{ s}^{-1}$ on 11 November, with the total
480 column water vapour increasing to just under 4 kg m^{-2} (Fig. 7a). The Foehn effect in this event
481 corresponds to that of cluster #1 (Fig. 4a), the more indirect pathway from the Weddell Sea as
482 opposed to Foehn events triggered by Pacific warm air intrusions (cluster #2, Fig. 4b).

483

484 As seen in Figs. 6c-d, the air mass accelerated downslope as it descended the mountains towards
485 coastal West Antarctica, with 10-m wind speeds higher than 20 m s^{-1} and in the top 10% of the
486 climatological distribution over a vast region including PIG (locally in the top 1% just to the
487 northwest and southeast of PIG), and downward sensible heat fluxes in excess of 75 W m^{-2} at PIG
488 (the negative, or upward pointing, fluxes around 75°S and 110°W are associated with a sea ice-
489 free area). These tendencies are seen in the area-averaged time-series (Fig. 7c) with the negative
490 (upward) latent heat flux indicating sublimation peaking on 11 November (Fig. 7f). In fact, the
491 phase of the latent heat flux matches that of the surface sublimation given in Fig. 7f. The opposite
492 sign of the sensible and latent heat fluxes, which roughly offset each other, is expected during
493 Foehn events (Elvidge et al., 2020), as the positive latent heat flux which arises due to sublimation
494 is opposed by the downward sensible heat flux due to the higher air than surface temperature. The
495 surface mass balance is essentially controlled by the surface and blowing snow sublimation, with
496 the precipitation/snowfall and the divergence terms playing a secondary role, and with the snow
497 melting being zero throughout the full period (Fig. 7f). The estimated maximum sublimation rate
498 is seen at the end of 10 November and has a magnitude of $\sim 0.13 \text{ mm w.e. hr}^{-1}$, comparable to the
499 ice loss due to ocean dynamics (e.g., Holland et al., 2007; Rintoul et al., 2016; Feldmann et al.,
500 2019) albeit in a non-sustained way. The ERA-5 snow depth, which accounts only for sublimation
501 and changes in snow density (snow melt is not simulated by ERA-5 during this event, Fig. 7f),
502 shows a steady decrease starting on 04 November and a faster drop from 11-13 November (not
503 shown). The reanalysis snow depth during this period is around 9.21 m w.e., within the range of
504 that observed during field campaigns discussed in Konrad et al. (2019). Besides sublimation,
505 melting was detected in the Moderate Resolution Imaging Spectroradiometer (MODIS; Kaufman
506 et al., 1997) satellite imagery reaching a maximum on 12 November (Fig. 7g). The melting area at
507 times exceeded $\sim 100 \text{ km}^2$ or roughly 2% of the central trunk of the glacier (Wingham et al., 2009).
508 The fact that ERA-5 does not simulate the observed melting can be attributed to the way snow
509 melting is parameterized in the model used to generate the reanalysis dataset, only taking place if
510 the temperature of the snow layer exceeds the melting point (ECMWF, 2016), with ERA-5
511 exhibiting a cold bias over the high terrain in Antarctica (e.g. Gonzalez et al., 2021). The observed
512 melting area is also much smaller than ERA-5's spatial resolution ($\sim 27 \text{ km} \times 27 \text{ km}$). Further
513 insight into the surface melt can be gained by running a surface balance model at high spatial
514 resolution that can be driven by ERA-5 data. This will be left for future work.

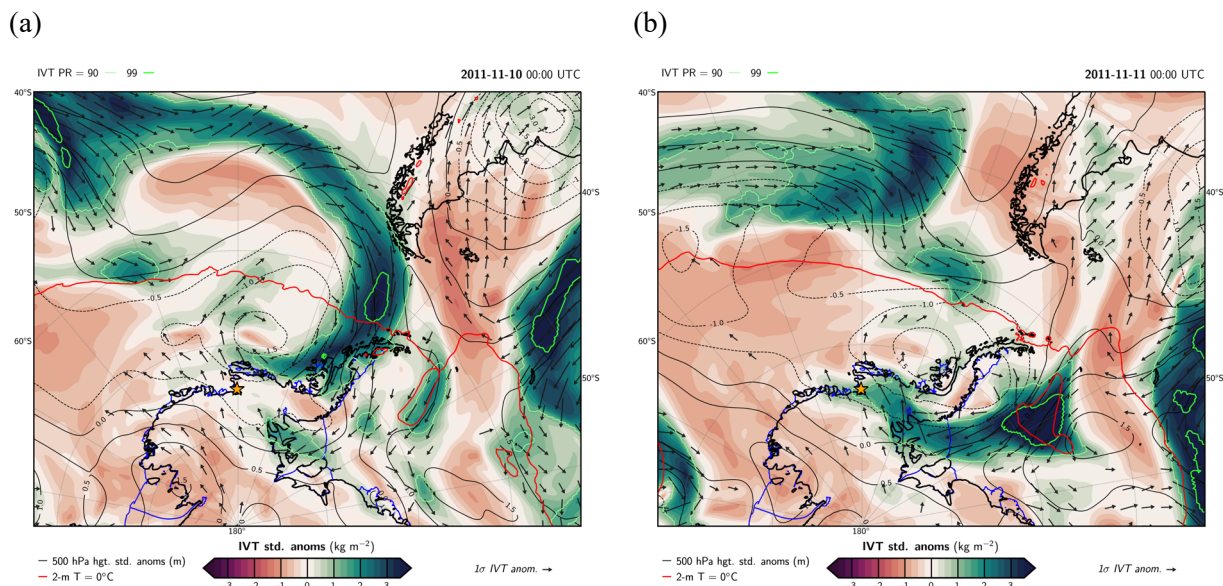

515

516 In Figs. 7d-e, the net shortwave, longwave and radiation fluxes from the reanalysis data are
517 compared with those estimated from satellite data, as given by the Clouds and Earth's Radiant
518 Energy System (CERES) SYN1deg dataset (Doelling et al. 2013, 2016). ERA-5 under-predicts
519 the net shortwave radiation flux during the day by up to a factor of 2.5, and the net longwave
520 radiation flux at night by up to 25 W m^{-2} . These differences are consistent with those reported by
521 Ghiz et al. (2021), who attributed the lower shortwave fluxes in ERA-5 compared to CERES to
522 differences in the cloud properties, with the reanalysis fluxes being more consistent with those
523 measured in situ at a site in the West Antarctic Ice Sheet than those of CERES. On the other hand,

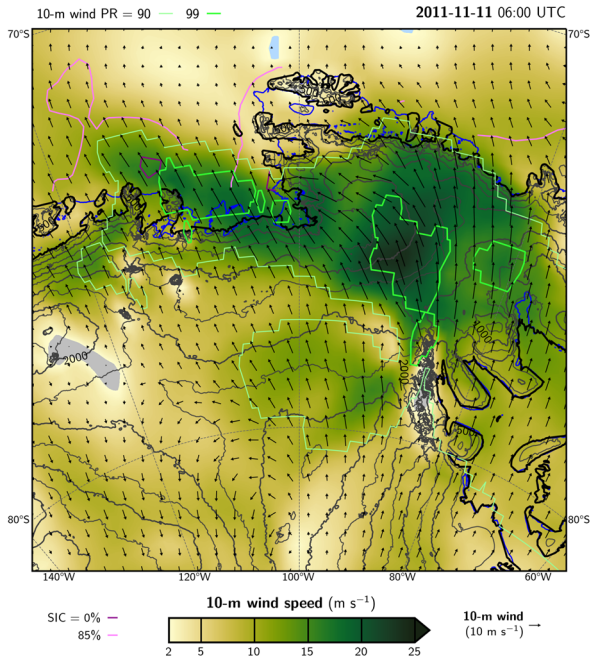

524 CERES partially corrects the tendency of ERA-5 to under-predict the net longwave radiation flux
 525 over Antarctica, in particular in clear-sky conditions (Silbert et al., 2019). During the November
 526 Foehn event, the area-averaged surface energy flux, F_{net} , is positive (Fig. 7e), as the positive
 527 sensible heat flux offsets the negative latent heat flux (Fig. 7c), and the surface net shortwave
 528 radiation flux overwhelms the negative net longwave flux (Fig. 7d). This indicates an excess of
 529 energy towards the surface leading to snow melt and evaporation. The 3-5°C increase in air
 530 temperature (Fig. 7b) with respect to the previous non-Foehn days, present both in the reanalysis
 531 and weather station data, is comparable to that seen during a Foehn event at the Ross Ice Shelf in
 532 January 2016 (Zou et al., 2019). Note that the ERA-5 values are area-averaged over the red box in
 533 Fig. 1a and hence the fields are likely larger in local areas.

534
 535 The Foehn event can also be seen in the Hovmoeller plots in Fig. 6e. The wind direction shifts
 536 from northeast to southeast on 08-09 November 2011 around PIG as the ASL moves closer to the
 537 Antarctica Peninsula. This is accompanied by an increase in the sensible heat flux, with a
 538 latitudinally-averaged value exceeding 50 W m^{-2} that corresponds to an anomaly of about 40 W m^{-2} .
 539 The fact that the peak in wind speed takes place $\sim 90^\circ\text{W}$ but that in the heat fluxes around 100° -
 540 110°W is consistent with the warming of the air mass as it descends the slopes of the mountains
 541 over West Antarctica. The drying of the atmosphere in association with the Foehn effects is also
 542 present, with the RH dropping below 70% during the event. The sensible heat flux shows a clear
 543 diurnal cycle, peaking around 05-06 UTC, which is roughly 00 Local Time (LT) for a longitude of
 544 $\sim 100^\circ\text{W}$, out-of-phase with the surface radiation fluxes (Figs. 7c-e). This mismatch is also seen on
 545 other days, and may be attributed to the effects of Foehn, clouds and moisture on the heat fluxes.
 546 Weaker Foehn events, with peak wind speeds roughly half of that on 09-11 November but similar
 547 values of RH, took place earlier in the month, on 03-04 November 2011.

548
 549

(d)

(e)

Figure 6: November 2011 Foehn events: Integrated Water Vapour Transport (IVT; $kg\ m^{-2}$; shading) standardized anomalies with respect to ERA-5's 1979-2020 monthly climatology, the vectors give a one standard deviation

anomaly and are only plotted if the IVT standardized anomalies exceed one, and 500 hPa geopotential height standardized anomalies (solid contours) on (a) 10 November and (b) 11 November 2011 at 00 UTC. The thin and thick green lines denote the 90th and 99th IVT percentiles, respectively, the yellow star gives the location of the Evans Knoll weather station (-74.85°S; -100.404°W), and the red solid line is the 0°C 2-m temperature isotherm. (c) 10-m wind speed (shading; m s^{-1}), with the 90th and 99th percentiles denoted by the solid thin and thick green lines, respectively, and 10-m winds (vectors; m s^{-1}) on 11 November 2011 at 06 UTC. The grey lines are orographic contours drawn and labelled every 500 m, and the dark solid purple and pink lines highlight regions where the sea-ice concentration is equal to 0% and 85%, respectively. (d) is as (c) but with the shading giving the sensible heat flux (shading; W m^{-2}), positive if downwards towards the surface. The anomalies and percentile ranks for the IVT, 10-m horizontal winds, 500 hPa geopotential height and 2-m temperature are calculated from the distribution of all 3-h values within ± 15 Julian days from the given date during the 1979–2020 period and at a given grid point. (e) Hovmoeller plot of sensible heat flux (shading; W m^{-2}) and relative humidity (contours, every 10%), sensible heat flux anomalies with respect to the 1979–2021 climatology (W m^{-2}), and 10-m wind direction ($^{\circ}$) and speed (m s^{-1}) for 01–15 November 2011. The fields are averaged over 72.5°–77.5°S and are plotted for the region 120°W–60°W. All colour bars are linear with only the lowest, middle and highest values shown. The black vertical line indicates the approximate longitude of PIG (100°W).

550

Figure 7: Impacts of Foehn winds on ice: Time series of 1-hourly ERA-5 variables averaged over PIG (red box in Fig. 1a) from 03 to 14 November 2011: (a) Integrated water vapor transport (IVT; light green; $\text{kg m}^{-1} \text{s}^{-1}$) and total column water vapor (TCWV; dark green; kg m^{-2}); (b) 10-min observed 2-m temperature (green; $^{\circ}\text{C}$) at the Evans Knoll weather station (-74.85°S , -100.404°W ; 188 m above sea-level), the anomalies with respect to the 2011-2015

hourly climatology are given by the dashed blue line, and area-averaged ERA-5 2-m temperature (red; °C); (c) ERA-5 sensible heat flux (SHF ; red; $W m^{-2}$) and latent heat flux (LHF ; orange; $W m^{-2}$); (d) net shortwave radiation (SW_{net} ; orange; $W m^{-2}$) and longwave radiation (LW_{net} ; red; $W m^{-2}$) flux at the surface; (e) net radiation (R_{net} ; blue; $W m^{-2}$) and total energy flux ($F_{net} = SHF + LHF + R_{net}$; red; $W m^{-2}$) at the surface; (f) individual components of the surface mass balance, Eq. (2), expressed in $mm w.e. hr^{-1}$. The S , P , M , Q_{surf} , Q_{snow} and D terms are given by the black, purple, red, green, orange and brown lines, respectively; (g) Daily total surface area (km^2) of melt ponds observed from MODIS imagery. In panel (c), the SHF anomalies, calculated as the difference from the domain-averaged 1979-2020 November hourly monthly mean, are also plotted. In (d)-(e), the net radiative variables from CERES averaged over the same domain are plotted as dashed lines for comparison. Times when Foehn occurred are shaded in blue.

551 6. Discussion and Conclusions

552 Pine Island Glacier (PIG), located in West Antarctica around 75°S and 100°W between the
553 Antarctic Peninsula to the east and the Ross Ice Shelf to the west, has been losing ice mass at an
554 accelerated rate over the last two decades. While the vast majority of the studies on ice loss at PIG
555 focus on ocean dynamics (e.g. Stanton et al., 2013; Favier et al., 2014), atmospheric forcing is also
556 likely to be important, with warmer and more moist air intrusions from the mid-latitudes and Foehn
557 effects the likely candidates (Ghiz et al., 2021). The role of moist air intrusions is well documented
558 (e.g. Willie et al., 2021), but less attention has been paid to Foehn, in particular around PIG where
559 the complex terrain promotes its occurrence. Foehn effects can lead to ice loss through
560 sublimation, which is typically a small-scale and invisible phenomenon in nature and hence
561 difficult to be detected using satellite data. At the same time, Foehn plays an important role in the
562 surface mass balance around Antarctica (Ghiz et al., 2021), and a better understanding of its
563 occurrence may help to reduce the major uncertainties that still exist (The IMBIE team, 2018). In
564 this work, a 41-year climatology of Foehn events at PIG is generated using ERA-5 reanalysis data,
565 and its impact on the surface mass balance is analyzed. The large-scale atmospheric circulation
566 patterns that favor Foehn events at PIG are also identified.

567
568 Foehn events at PIG are more frequent in the colder months from June to October, with an
569 average of 3.0 events per month in the 105°-95°W and 70°-80°S region in August 1980-2020 and
570 just 0.37 in January. The peak in austral winter is consistent with the poleward position of the mid-
571 latitude storm track, with the Amundsen Sea Low (ASL), a semi-permanent low pressure in the
572 Amundsen-Bellingshausen Seas, closest to the Antarctica coast in late winter. The presence of a
573 low just north of PIG favours easterly to southeasterly winds at the site, which encourages the
574 occurrence of Foehn. The duration of Foehn events exhibits a less pronounced annual cycle, with
575 Foehn episodes typically lasting 5 to 9 h. The negative phase of the Antarctic Oscillation, in
576 particular in the cold season (May to August), and the positive phase of the Southern Annular
577 Mode, foster the occurrence of Foehn at PIG. The former is a more indirect pathway, with the air
578 flow coming from the Weddell sector and moving over the Ellsworth Land before reaching PIG,
579 while in the latter the air mass comes from the Pacific Ocean and flows over the high terrain
580 directly to the northeast of PIG before descending into the glacier basin.

581

582 A composite of Foehn and no-Foehn episodes revealed that Foehn events have an important impact
583 on the surface mass balance. It is concluded that surface sublimation plays the major role, with a
584 magnitude of ~ 1.434 mm water equivalent (w.e.) day^{-1} , comparable to that observed at other sites
585 in Antarctica. The blowing snow sublimation and divergence rate have a comparable magnitude
586 to that of the precipitation (snowfall) rate, with values of 0.35-0.36 mm w.e. day^{-1} . However, while
587 the former makes a positive contribution to the surface mass balance due to the convergence of the
588 snow transport rate at the glacier basin, the latter depletes surface snow, as the drier conditions
589 associated with Foehn reduce the likelihood of the occurrence of precipitation. The melting rate is
590 negligible and is restricted to the coastal areas to the north of the glacier.

591
592 A particularly strong Foehn event took place on 09-11 November 2011. During this period the
593 ASL was more than 1.5 standard deviations stronger than the 1979-2020 climatological mean, with
594 an atmospheric river from the Southeast Pacific injecting moisture into West Antarctica through
595 the Weddell Sea. As the southeasterly winds descended the high terrain east and southeast of the
596 glacier they accelerated, with 10-m wind speeds in excess of 20 m s^{-1} and in the top 10% of the
597 climatological distribution, and downward sensible heat fluxes higher than 75 W m^{-2} , a clear
598 signature of Foehn effects. Besides surface sublimation, at a rate of up to $0.13 \text{ mm w.e. hr}^{-1}$, melting
599 was detected using satellite data with the hourly melting area at times in excess of 100 km^2 .

600
601 As Foehn has been shown to play an important role in modulating ice conditions elsewhere
602 around Antarctica such as in the Antarctic Peninsula (Massom et al., 2018) and Ross Ice Shelf
603 (Zou et al. 2021a and b), a detailed analysis of Antarctica-wide Foehn occurrence is needed to
604 better quantify its contribution to snow sublimation and ice loss. The fact that Foehn winds are
605 more effective in inducing snow sublimation than snow melt at PIG, makes it challenging to detect
606 their total impact on the ice state at the scale of the continent as snow evaporation cannot be
607 detected from space. Advanced remote sensing techniques to detect changes in the depth of the
608 snow layer over land ice are therefore needed.

609 **Acknowledgment**

610 The authors wish to acknowledge the contribution of Khalifa University's high-performance
611 computing and research computing facilities to the results of this research. This work has been
612 supported by Masdar Abu Dhabi Future Energy Company through research grant number
613 8434000222. We also appreciate the support of the University of Wisconsin-Madison Automatic
614 Weather Station Program for the data set and information, NSF grant number 1924730. We would
615 like to thank the two anonymous reviewers for their insightful and constructive comments and
616 suggestions that have substantially improved the quality of this manuscript.

617 **Code Availability**

618 The scripts used to process MODIS data and estimate the melting area are available upon request
619 from Dr. Catherine Walker (catherine.c.walker@nasa.gov). The codes used to estimate the terms
620 in the surface mass balance can be requested from Prof. Diana Francis (diana.francis@ku.ac.ae).

621 **Data Availability**

622 All the data used to generate the figures in this study has been uploaded to Francis et al. (2023).
623 ERA-5 hourly reanalysis surface (Hersbach et al. 2018b) and pressure-level (Hersbach et al.
624 2018a) data used in this work is freely available online on Copernicus' Climate Change Service
625 Climate Data Store website. The weather data for the Evans Knoll station located next to Pine
626 Island Glacier (PIG) is freely available at the Antarctic Meteorological Research Center &
627 Automatic Weather Stations Project website (Lazzara et al., 2022). The Antarctic 1 km Digital
628 Elevation Model (DEM) from Combined ERS-1 Radar and ICESat Laser Satellite Altimetry,
629 Version 1 (NSIDC-0422; Bamber et al. 2009a) used to plot Antarctica surface elevation,
630 MEaSURES InSAR-Based Antarctica Ice Velocity Map, Version 2 (NSIDC-0484; Rignot et al.
631 2017) used to plot mean ice velocity of Pine Island and Thwaites Glaciers, and MEaSURES
632 Antarctic Boundaries for IPY 2007-2009 from Satellite Radar, Version 2 (NSIDC-0709; Mougintot
633 et al. 2017) are freely available available from the National Aeronautics and Space Administration
634 National Snow and Ice Data Center (NSIDC) Distributed Active Archive Center website. The
635 Clouds and Earth's Radiant Energy System (CERES) surface fluxes product SYN1deg - Level 3 has
636 been made publicly available at NASA/LARC/SD/ASDC (2017). Sentinel-2 satellite data, used to
637 extract the sea-ice front at PIG, is available online at (Copernicus, 2022). The MODIS daily global
638 surface reflectance Level 3 data (MOD09CMG, MYD09CMG; Vermote 2015a,b) are publicly
639 available from NASA Earthdata. The figures presented in this paper were generated using the
640 Interactive Data Language (IDL; Bowman, 2005) software version 8.8.1 and the Matplotlib
641 (Hunter, 2007) and Cartopy (Met Office, 2014) python libraries.

642 **Author Contribution**

643 DF conceived the study. RF and DF wrote the manuscript with inputs from KSM, SL and CW. SL
644 and CW processed the MODIS data while RF and KSM analyzed the reanalysis data. DF provided
645 formal analysis and validation of the results.

646

647 **Conflict of Interest**

648 SL is a member of the editorial board of The Cryosphere and this is handled according to the
649 journal policies.
