Abstract. Winter warm air intrusions entering the Arctic ~~ocean-region~~ can strongly modify the microwave emission of the snow/ice system due to temperature induced snow metamorphism and ice crust formations e.g., after melt-refreeze events. Common microwave radiometer satellite sea ice concentration retrievals are based on empirical models using the snow/ice emissivity and thus can be influenced by strong warm air intrusions. Here, we carry out a long-term study analyzing 41 years of ~~winter~~ sea ice concentration observations from different algorithms to investigate the impact of ~~warming-events-warm air intrusions~~ on the retrieved ice concentration. Our results show that three out of four ~~analyzed-sea-ice-concentration-retrievals algorithms~~ underestimate the sea ice concentration during ~~(and up to 10 days after)~~ warm air intrusions which increase the 2 m air temperature ~~(daily maximum)~~ above -5°C . This can lead to sea ice area underestimations in the order of 10^4 to 10^5 km². If the 2 m temperature during the warm air intrusions ~~cross-crosses~~ -2°C , all ~~retrieval-methods-algorithms~~ are impacted. Our analysis shows that the strength of these strong warm air intrusions increased in recent years, especially in April. ~~Within the scope of future-With a further~~ climate change, ~~it is expected that~~ such warm air intrusions ~~will occur even are expected to occur~~ more frequent and ~~also~~ earlier in the season and ~~thus the influence of these warm air intrusions~~ ~~their influence~~ on sea ice ~~climatologies-climate data records~~ will become more important ~~in future~~.

1 Introduction

Sea ice concentration estimates from passive microwave satellite observations are an important data set for observing and understanding the Arctic climate system and for monitoring its recent drastic changes (e.g., Perovich et al., 2017; Maslanik et al., 2011; Kumar et al., 2010). Long term, inter-calibrated ~~time-series-of~~ sea ice concentration ~~;-so-called-climate-data-records (CDR)-provided-by-data-sets-provided-by-e.g.;~~ the National Snow and Ice Data Center (NSIDC) (Meier et al., 2021) and the Ocean and Sea Ice Satellite Application Facility (~~OSI-SAFOSI SAF~~) (Lavergne et al., 2016, 2019), are of special value since they provide consistent, more than 40 years long time series of Arctic sea ice cover. They naturally have a rather coarse spatial resolution in the order of 25 km². Methods like the ~~ASI-ARTIST Sea Ice (ASI)~~ algorithm (Spreen et al., 2008) utilizing observations at a higher microwave frequency at 89 GHz (available since 2002 for AMSR-E/2) ~~take-advantage-of-their-which has a~~ higher spatial resolution (6.25 km² grid resolution for AMSR-E/2).

Even after decades of research, accurate estimation of sea ice concentration and thus sea ice area remain challenging, especially in summer (~~Ivanova et al., 2015; Liu and Curry, 2003; Tonboe et al., 2003, e.g.-)~~

(Ivanova et al., 2015; Kern et al., 2019, 2020, 2022; Liu and Curry, 2003; Tonboe et al., 2003, e.g.). In winter and spring, atmospheric warm air intrusions, which increased in intensity and frequency in recent years (Graham et al., 2017), can influence not only the sea ice conditions due to dynamic and thermodynamic processes (Aue et al., 2022; Clancy et al., 2021; Graham et al., 2019b) but also influence the microwave signal of the snow/ice system due to rapid snow metamorphism and melt-refreeze events

~~(Comiso et al., 1997; Drinkwater et al., 1995; Rückert et al., 2023; Tonboe et al., 2003). Consequently, warming events can~~
~~(Comiso et al., 1997; Drinkwater et al., 1995; Kern et al., 2020; Rückert et al., 2023; Tonboe et al., 2003). Of importance is that the impact of snow warming, snow metamorphism and snow surface changes due to melt-refreeze events can be visible in the microwave signal for several days and up to weeks after the event (e.g., Rückert et al., 2023). Consequently, warm air intrusions~~
can impact the quality of satellite sea ice concentration retrievals. Rückert et al. (2023) investigated the impact of such a warm air intrusion along the MOSAiC campaign in the central Arctic in April 2020 and found a strong drop in retrieved ice concentration ~~due to caused by~~ the formation of a large-scale surface ice glazing-glazed ice layer on top of the snow.

The aim of this study is to I) analyze how strong the impact of winter warm air intrusions on the retrieved sea ice concentration is and II) whether the impact ~~is increasing-increased~~ in recent years due to an increase frequency of strong warm air intrusions entering the Arctic ~~Ocean region~~. We hereby analyze four common sea ice products: The ~~NSIDC (Meier et al., 2021) and OSI-SAF (Lavergne et al., 2016, 2019)~~ National Snow and Ice Data Center (NSIDC) (Meier et al., 2021, version 4) and Ocean and Sea Ice Facility (OSI SAF) (Lavergne et al., 2016, 2019, version 3) climate data records (CDR), as well as the ASI (Spren et al., 2008) and the NASA-Team (here used: the product provided within the NSIDC CDR) sea ice concentration algorithms. ~~The first two are climate data records that means they provide a consistent, quality proved long-term time-series of sea ice concentration. The ASI algorithm utilizes higher frequencies and thus a higher spatial resolution and is available since 2002.~~

The article is organized ~~the following. In chapter as follows. In section~~ two, the ~~physical background of microwave emission of the snow-sea ice system is briefly discussed. The four satellite-based sea ice algorithms and other auxiliary data are introduced~~ basics of passive microwave sea ice concentration algorithms are briefly introduced and the data sets used in this study are described. The method to detect and define warm air intrusions is described in ~~chapter section~~ three. In ~~chapter section~~ four, the main results are presented and in ~~chapter section~~ five, the uncertainty and possible error sources of the results are discussed. In addition, a detailed discussion of the performance of the NSIDC and OSI SAF CDR products is provided. The article closes with a conclusion.

2 ~~Passive microwave sea ice concentration algorithms~~Data sets

Passive microwave satellite sensors are a common tool to observe the sea ice in the Arctic and Antarctic ocean. To first order, sea ice concentration algorithms take advantage of the strong emissivity difference between sea ice ($\epsilon > 0.8$, depending on the frequency) and sea water ($\epsilon < 0.3$), which make the two ~~quantities~~ surfaces easily distinguishable. In addition, the polarization difference and emissivity changes with frequency can be used to distinguish ice and water. Different algorithms use different

methods and frequencies to relate the observed emissivity to sea ice concentration.

60

In general, the emissivity of sea ice depends on the physical quantities of the ice and snow as well as on the microwave frequency. In Spreen et al. (2008), Figure 1, the typical emissivity of different surface types (first-year ice, multiyear ice and open ocean) are shown in dependence of typical microwave frequencies used by satellites and most of the common sea ice concentration retrievals. ~~However, several studies have shown that strong weather events like warm air intrusions, introducing snow metamorphism, melt-refreeze events or liquid water formation in the snow, influence~~ However, the emissivity of the snow/ice system (Liu and Curry, 2003; Rückert et al., 2023; Stroeve et al., 2022; Tonboe et al., 2003, e.g.). ~~The emissivity of the snow/ice system~~ depends on many parameters. ~~However, the~~ The main drivers are snow/ice temperature, ice type and the snow microstructure. Ice layers within or ice crusts at top of the snowpack can influence sea ice concentration retrievals that use polarization differences or ratios (due to their strong impact on horizontal polarization, Comiso et al. (1997); Mätzler et al. (1984)). At frequencies higher than 19 GHz, also parameters like snow grain size and shape become important ~~influencing influences for~~, e.g, retrievals that use gradient ratios of two different frequencies. ~~Strong changes in the~~

Several studies have shown that strong weather events like warm air intrusions, introducing snow metamorphism, melt-refreeze events or liquid water formation in the snow modify the above mentioned parameters ~~influence these quantities and thus~~ and consequently influence the emissivity of the snow/ice system (e.g., Liu and Curry, 2003; Rückert et al., 2023; Stroeve et al., 2022; Tonboe et al., 2003). Therefore, warm air intrusions can introduce false changes in the retrieved SIC (Tonboe et al., 2003, e.g.). Figure 4 in (Rückert et al., 2023) (see also Figure B1) sea ice concentration (e.g., Tonboe et al., 2003).

Figure B1 (figure 4 from Rückert et al., 2023) in the appendix shows the temporal evolution of brightness temperatures and derived parameters for a warm air intrusion in April 2020. A strong impact on the brightness temperatures at higher frequencies (19 GHz – 89 GHz) is visible during the events while the polarization difference and ratio (which are used in the sea ice retrievals analyzed in this study) show a strong increase just after the warming events due the formation of a large-scale glazed ice layer on top of the snow. The gradient ratio shows a strong increase during the events. It remains higher after the event indicating that snow metamorphism led to stronger scatterer influencing the higher frequencies. In this study, as already mentioned, four different sea ice concentration products are analyzed. The Ocean and sea ice facility (OSI-SAFOSI SAF) (Lavergne et al., 2016, 2019) and National Snow and Ice Data Center (NSIDC) (Meier et al., 2021) algorithms are so called climate data records (CDR) ~~and provide a stable time series of more than 40 years. In addition,~~ CDRs are designed to provide consistent, reproducible long-term timeseries of climate variables. Long term sea ice concentration is also provided by e.g., the NASA-Team algorithm (Cavalieri et al., 1997) ~~is analyzed since it which~~ is frequently used and is part of the NSIDC CDR. All these retrievals utilize microwave frequencies between 6.9 GHz and 36.5 GHz. Additionally, we analyze the performance of the ASI algorithm (Spreen et al., 2008) which is based on 89 GHz. All algorithms are re-sampled to a 25-25 km² polar stereographic grid which is the resolution of the coarsest product.

2.0.1 ~~NSIDC climate data record~~

2.1 NSIDC climate data record

95 More than 40 years of consistent sea ice concentration observations from various satellites is provided by the NSIDC (~~Meier et al., 2021~~)
(Meier et al., 2021, version 4). Daily sea ice concentration is estimated from combining two different products, i.e., the NASA-
Team (Cavalieri et al., 1997) and Bootstrap (Comiso, 1986) algorithms. For the final product, the higher sea ice concentration
of the two sub-algorithm is used on a grid-cell level. The ~~algorithm is~~ sub-algorithms are based on brightness temperature ob-
servations at 19 GHz and 37 GHz at both polarizations horizontal (H) and vertical (V). The Bootstrap algorithm uses dynamic
100 (daily) tiepoints to mitigate the impact of brightness temperature variability (Comiso et al., 2017). A full description of the
product can be found at <https://nsidc.org/data/g02202/versions/4>. The resolution of this product is ~~25-25~~ 25 × 25 km². An un-
certainty estimation is given for an individual grid cell based on the spatial variability within the 9 surrounding grid cells of
both sub-algorithms.

2.1.1 ~~OSI-SAF climate data record~~

105 ~~OSI-SAF~~

2.2 OSI SAF climate data record

OSI SAF provides daily sea ice concentration based on a dynamic algorithm (Lavergne et al., 2016, 2019). Brightness tem-
peratures at 19V, 37V and 37H are used to estimate daily sea ice concentration values at ~~25-25~~ 25 × 25 km² resolution. OSI
SAF includes ERA5 reanalysis data for correcting atmospheric effects on the brightness temperature observations. The un-
110 certainty in sea ice concentration is estimated combining the uncertainty of the algorithm itself and the “smearing” uncer-
tainty due to the daily ~~redding~~ gridding of several orbits for the final product. A full description of the product is provided at
<https://OSISAF.eumetsat.int/products/osi-450-a>. The reference to the data set is osi-450-a (2023).

2.2.1 ~~ASI~~

2.3 ASI

115 The ASI algorithm estimates the sea ice concentration from passive microwave satellite observations from AMSR-E and
AMSR2 at 89 GHz. It is based on a empirical equation relating the polarization difference (i.e., brightness temperatures at V-
Pol – H-Pol) to sea ice concentration (Spreen et al., 2008). The spatial resolution of this product is ~~6.25-6.25~~ 6.25 × 6.25 km²
Additional weather filters using lower frequencies are applied to reduce the impact of clouds and water vapor over the open
ocean on the retrieved ice concentration. The uncertainty is dependent on the ice concentration and is around 5% in the high
120 ice concentration regime.

2.4 NASA-Team

~~In addition, we analyze the~~ The NASA-Team ice concentration algorithm (Cavalieri et al., 1997) which is provided within the NSIDC CDR data set. It is based on a combination of polarization ratio at 19 GHz and the gradient ratio of 37 GHz and 19 GHz (V polarization). No additional uncertainty estimation for the NASA-Team sub-algorithm is provided.

125 2.4.1 ~~Auxiliary Data~~

2.5 ERA5

In this study, 2 m air temperature from ~~ERA-5~~ ERA5 (Hersbach et al., 2020) reanalysis data are used to detect warm air intrusions. Here the daily maximum of the temperature is used ~~ERA-5~~ (refereed to as daily max., hereafter). ERA5 is known to have a positive temperature bias in the Arctic (~~Herrmannsdörfer et al., 2023, e.g.,~~)
130 (Batak and Müller, 2019; Herrmannsdörfer et al., 2023; Wang et al., 2019). Possible consequences are discussed in section 5.1.

3 Warm air intrusion detection algorithm

~~A detailed description of the algorithm is given in Appendix 3, here only a brief overview of the most important details is provided~~

135 3.1 Overview of procedure

Here, we describe the algorithm used in this study. The algorithm is build to detect connected areas where the daily max. 2 m air temperature ~~(from ERA5; Hersbach et al. (2020))~~ (from ERA5; Hersbach et al., 2020) crosses a certain threshold within a given time window. ~~Table 1 summarizes the conditions that need to be fulfilled for the~~

140 An overview of the procedure of the algorithm to detect warm air intrusions is given in Figure 1. The input for the detection algorithm are 30-days arrays of gridded ERA5 daily max. 2 m air temperature (T2m). We defined the following categories for the temperature thresholds: category 1: $-10^{\circ}\text{C} < T \leq -5^{\circ}\text{C}$, category 2: $-5^{\circ}\text{C} < T \leq -2^{\circ}\text{C}$, and category 3: $T > -2^{\circ}\text{C}$ (in the following, for simplicity we will refer to category 1 as $T > -10^{\circ}\text{C}$ and to category 2 as $T > -5^{\circ}\text{C}$). The *Threshold detection* procedure detects connected areas where the temperature reaches one of the categories for a certain amount of days
145 (here used: 2 days). The algorithm can detected several not-connected warm air intrusions~~being considered in this study. An initial temperature threshold~~. If their borders are separated by 2 pixels (= 50 km) or less, the intrusions will be merged.

The choice of the three different categories is motivated as following. We do not expect strong snow metamorphism for category 1 warm air intrusions and thus changes in sea ice concentration in this category are likely due to sea ice dynamics.
150 Assuming similar sea ice dynamics across the three different categories, a stronger drop in SIC in category 2 or 3 compared to category 1 is consequently likely due to snow metamorphism. For the warmest category 3, also strong surface changes due to

e.g., melt-refreezing events can be expected.

155 In a first step, a temperature threshold for an initial detection of a potential warm air intrusion is set at -10°C . In addition $T \geq -10^{\circ}\text{C}$. Especially in the marginal ice zone, the daily 2 m max. air temperature can sometimes fluctuate from day-to-day around this threshold even if no WAI is present. In order for the WAI to be further considered, the duration of the wave during which the temperature threshold during which this temperature threshold is crossed must be at least two days in order to avoid short-term fluctuation around the threshold close in the marginal ice zone consecutive days. A minimum ΔT of 5 K between the peak temperature and background temperature is chosen to ensure that a real warm air intrusion is detected and exclude cases where the temperature only fluctuates around a threshold (e.g., in late spring where the average temperatures can easily be above -10°C). Similarly, a minimum size of the detected area of $200\text{-}200\text{ km}^2$ is required. We use April 30 as the end of the algorithm since afterwards, average temperatures are too high for reliable warm air intrusions detection. Last, a window of 30 days is chosen, which ensures that the whole Table 1 summarizes the set of conditions for the initial detection of a warm air intrusion is captured.

165 The procedure of During the detection, a land mask, a polynya mask, and a dynamic ice edge mask are applied. The ice edge mask is derived from the minimum extent of SIC $> 65\%$ during the 30-day period. By analyzing all warming events, we found that the sea ice concentration in the Central Arctic from the OSI SAF algorithm never drops below 65% in the areas affected by a WAI. Thus, this number is a good compromise in order to include as many warm air intrusions as possible while reducing the effect of a moving ice edge on the results. For the polynya mask, we analyzed 41 years of winter OSI SAF sea ice concentration and masked out areas where the SIC frequently ($> 15\%$ of the days) dropped below 50% while the ice edge was far away. Masked out areas are, e.g., around Svalbard or Novaya Semlya (see Figure 2).

170 the Threshold detection interacts with the the algorithm is summarized in Figure 1. I) We apply the algorithm for a period of 30 days and then compute the whole time series from November 1 to April 30 for each winter season with a slicing window of 5 days (i. e., Similarity check procedure. Here, it is tested if the current detected warm air intrusions are similar to the previously detected ones. First, the overlapping area of the new and previous warm air intrusion is calculated. If the overlap is above 70%, the detection algorithm is run for the time period November 01 to November 30, then for the time period for November 06 to December 05, etc.). II) For each 30-day period, areas are detected where the temperature crosses at least one of the following thresholds: $> -10^{\circ}\text{C}$, $> -5^{\circ}\text{C}$ or $> -2^{\circ}\text{C}$ larger intrusion is used for further calculations and the other one is discarded. If the extent of both intrusions is similar, the warm air intrusion with the larger effective area reduction (see section 3.2) is used.

180 In the following, these thresholds are referred to as warming events of category 1 to 3. We do not expect strong snow metamorphism for category 1 waves and thus changes in next step, the detected areas are combined with the sea ice concentration within this area are likely due to sea ice dynamics. Assuming similar sea ice dynamics across the three different categories, a stronger drop in SIC in category data sets and the procedure Effective area reduction is applied. In this module, the effective area reduction (see section 3.2) is calculated for each sea ice concentration data set and for each defined threshold. The data is finally stored in the Output array. In this study, the algorithm is applied for the winter season November – April. With a 5

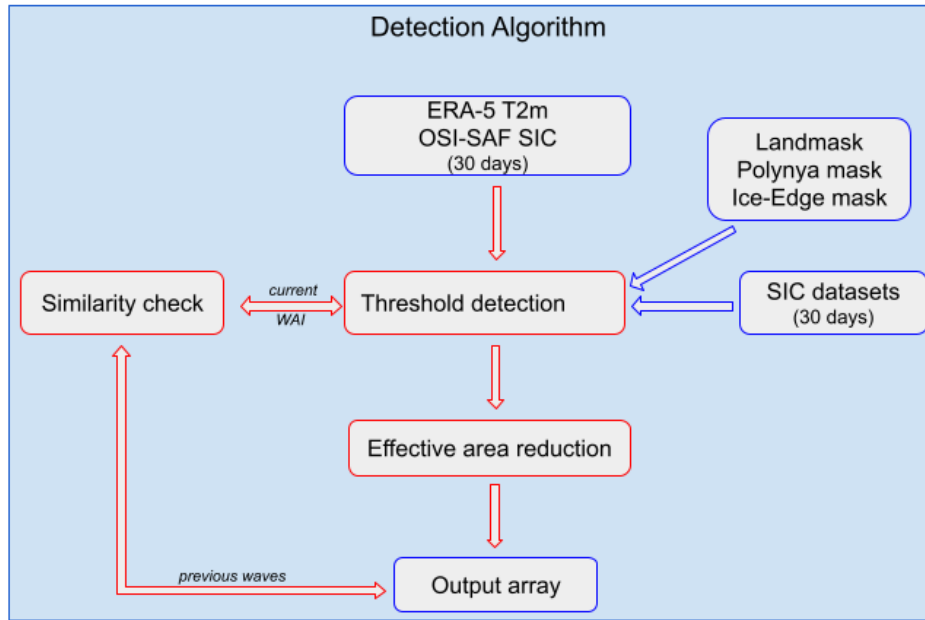

Figure 1. Overview of the warm air intrusion detection algorithm. Here WAI is the abbreviation for warm air intrusions.

day time step, in each iteration, 30 days of 2 or 3 compared to category 1 is consequently likely due to snow metamorphism. III) Several corrections and additional checks are applied (see appendix 3) and the so-called "effective area loss" is calculated based on the reduction of m max. air temperature and sea ice concentration due to the warming event (see appendix 3.2) are analyzed. A sensitivity test showed that a 5 day step is needed to ensure that the warm air intrusions is optimally captured while the processing time of a season remains reasonably short.

3.2 Effective area reduction

In order to break the impact of the warm air intrusions on the sea ice concentration to down one number, the "effective area reduction" is defined. This parameter describes the effective area reduction due to a reduction of sea ice concentration during the period impacted by a warm air intrusion in comparison to the reference sea ice concentration before and after the event. Figure 3 shows the basic principle of this calculation. Shown are the sea ice concentration and the daily max. 2 m air temperature averaged over the area where the threshold $> -5^{\circ}\text{C}$ was crossed. The maximum affected area by this warm air intrusion was around $2 \cdot 10^6 \text{ km}^2$. The average sea ice concentration is above 99% before and after the event and drops to 95% during the warm air intrusion (red). The resulting effective area reduction, i.e., the sum of the differences between SIC reduced and the average reference SIC, is $6 \cdot 10^5 \text{ km}^2$ over the whole red period (16 days) or $\approx 2\%/day$.

Defining the time period during which the sea ice concentration is affected by the warm air intrusion is not straight forward. In this study, the following procedure was chosen: The start of the affected period (SIC reduced) is based on the day, when the daily max. 2 m air temperature first crossed the $> -10^{\circ}\text{C}$ mark. The end of the period is reached when the sea ice concentration

Figure 2. Extended landmask used in the algorithm. Grey areas indicate the landmask and red areas indicate the area where the polynya mask is applied.

Table 1. Parameters for the initial warm air intrusions detection. T_{max} is the threshold of the temperature maximum that needs to be crossed to trigger the algorithm. T_{th} is the threshold temperature of the three different warm air intrusion categories. ΔT is the temperature difference between the T_{max} and the background temperature (i.e., the average temperature prior and after the warming event). A minimum size of $200 \cdot 200 \text{ km}^2$ (of connected warming) is required. Time period describes the period where the algorithm is applied and window the range of days the data is analyzed for.

Quantity	Condition
T_{max}	$> -10^{\circ}\text{C}$
T_{th}	$> -10^{\circ}\text{C} / > -5^{\circ}\text{C} / > -2^{\circ}\text{C}$
Duration	> 2 days
ΔT	> 5 K
Size	<u>$\geq 200 \cdot 200 \text{ km}^2$</u>
Time period	Nov 01 - Apr 30
Window	30 Days

is close (within 1%) of the reference sea ice concentration. If the latter does not apply, the end of the affected period is set to 10 days after the maximum of the SIC reduction. 10 days was chosen manual by analyzing several detected warm air intrusions. We found that most of the times, after 10 days, the effect of warm air intrusions on the sea ice concentration is negligible. The reference SIC (blue lines) is the average of the sea ice concentration before and after the warming events. In this example, the drop in SIC around day 10 is related to a different WAI and thus excluded in the analysis.

3.3 Sensitivity of choice of detection parameters

We note that the calculated effective area reduction is depending on the choice of parameters (reference periods, affected period, iteration step length). We performed a sensitivity study varying the controlling parameters for five test warm air intrusions to estimate their impact on the effective area reduction. In the example given in Figure 3, varying the start and end dates for the affected period (red line) by ± 2 days would lead to changes in effective area reduction of around 5%. Varying the selection of the reference period in a similar way led to changes of around 3%. Reducing the iteration step to 1 day instead of 5 days to find the optimal window for the warm air intrusions did not lead to relevant changes for the example shown above. Analyzing 5 selected large warm air intrusions (March 1990, December 2016, April 2015 and 2020, and February 2020), on average, the effective area reduction varied by $\pm 6\%$ due to varying the reference periods and affected periods as described above. In two cases, optimizing the warm air intrusion detection by using an iteration step length of 1 day increased the effective area reduction by more than 3% and 7%, respectively. For the other cases, no relevant changes were observed. In conclusion, an uncertainty in effective area reduction of roughly 5% can be expected introduced by using fixed parameters for the warm air intrusion detection.

4 Results

4.1 Example of Warming Events

In this section, two strong warm air intrusions are discussed in detail. These two exceptional warm air intrusions crossed the majority of the sea ice covered Arctic in April 2015 and April 2020 (Figure 4 and 5). For both warm air intrusions, temperatures crossed -5°C for a large fraction of the area influenced by the warming wave (orange) and -2°C in some areas (red). Figure 4 top left shows the maximum extent where the warming peak crossed the different temperature categories. White color refers to the sea ice cover which is not influenced by the warm air intrusion and blue to the open ocean. In the first row, panel 2 to 5 show the sea ice concentration from four different algorithms, averaged over the whole area affected (all categories, panel 2), the area with $-10^{\circ}\text{C} < T < -5^{\circ}\text{C}$ (panel 3), the area with $-5^{\circ}\text{C} < T < -2^{\circ}\text{C}$ (panel 4), and the area with $T > -2^{\circ}\text{C}$ (panel 5), respectively. In the second row, the left panel shows the average daily max. air temperature for the whole area influenced by the warm air intrusion (i.e., where the warming crossed -10°C), with gray shading indicating the 10 and 90 percentiles. Row 2 to 5 show sea ice concentration retrieved by the different algorithms. The day shown refers to the minimum

Figure 3. [Example for the effective area reduction calculation.](#) The sea ice concentration is an average over the whole area affected by the warm air intrusion (around $2 \cdot 10^6 \text{ km}^2$). Gray shading indicate the 10 and 90 percentiles of the daily max. 2 m air temperature.

235 sea ice concentration in the $-5^\circ\text{C} < T < -2^\circ\text{C}$ category. This day can be different for the individual algorithms (see individual maps).

At its maximum extent, the warm air intrusion covered the Fram Strait as well as most parts of the central Arctic, overall, [extending to](#) an area of $337 \cdot 10^4 \text{ km}^2$. The strongest drop in sea ice concentration by the [OSI-SAF-OSI SAF](#) and NASA-Team algorithms happened in the area where the temperature crossed -2°C . However, the area covered by this category is small. The overall impact on the sea ice area is largest for category 2 for all algorithms. The effective area [loss-reduction](#) (i.e., the overall reduction of sea ice area due to sea ice concentration underestimations; see [appendix-section 3.2](#)) is calculated for the days from April 16 to April 26 and is $52 \cdot 10^4 \text{ km}^2$ for the NASA-Team, [75–10⁴78 · 10⁴ km²](#) for the [OSI-SAF-OSI SAF](#) and $112 \cdot 10^4 \text{ km}^2$ for the ASI algorithm. The overall loss for the NSIDC CDR is small ($< 8 \cdot 10^4 \text{ km}^2$). For individual days, the effective area [loss-reduction](#) can be up to $9 \cdot 10^4 \text{ km}^2$ for the [OSI-SAF-OSI SAF](#) algorithm and $19 \cdot 10^4 \text{ km}^2$ for the ASI algorithm. For the first category, i.e. at -10°C , the influence of the warm air intrusion is small for all retrieval algorithms (e.g., $< 10 \cdot 10^4 \text{ km}^2$ for the [OSI-SAF-OSI SAF](#) algorithm).

Figure 5 shows the same as Figure 4 but for a warm air intrusion reaching the Arctic in April 2020. This warm air intrusion is described in detail in Rückert et al. (2023). The authors attributed the false reduction in sea ice concentration to the formation of a large-scale glaze ice layer, lasting more than a week after the warming event. The real sea ice concentration remained close to 100% in the Central Arctic during and after the warming [eventsair intrusion](#). In the warming category 2, the performance

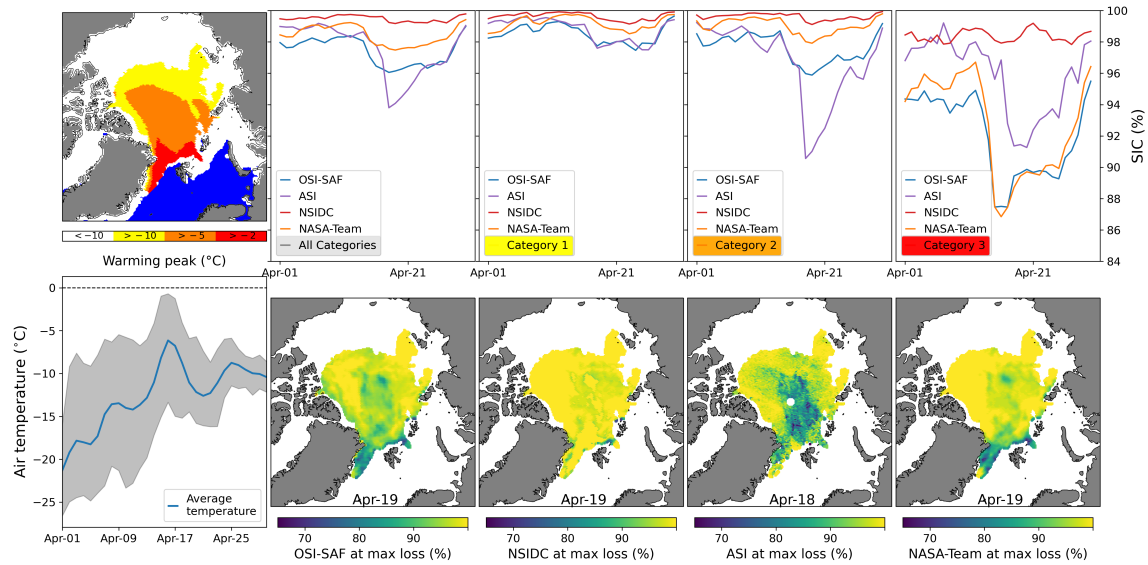

Figure 4. April 2015 warm air intrusion and its influence on the four different sea ice concentration products. Top panel shows the extent of the warm air intrusion subdivided into three temperature categories, i.e. $-10 \leq -10^{\circ}\text{C}$, $-5 \leq -5^{\circ}\text{C}$, and -2°C (left) for the time period between April 01 and May 01, and the average sea ice concentration for each category. Bottom panel (left) shows the Average air temperature for the whole area influenced by the warming event (i.e., daily max 2 m air temperature $> -10^{\circ}\text{C}$). Gray shading indicates the 10 and 90 percentiles. Columns 2 – 5 show the sea ice concentration for the different retrievals for the day when their respective ice concentration for the influenced area is lowest (the minimum ice concentration is calculated for the $T > -5^{\circ}\text{C}$ category). The date is given in the figure.

250 of the different algorithms is similar to the 2015 warm air intrusion discussed before, except for the NASA-Team algorithm, which shows a stronger response compared to the previous discussed warm air intrusion. It is interesting to note that while the sea ice concentration starts recovering for the ASI algorithm towards the end of April, both the NASA-Team and ~~OSI-SAF~~ ~~SIC~~ ~~remains~~ ~~OSI SAF~~ ~~SIC remain~~ reduced indicating that the effect of the warming event might last longer for these algorithms. In the third category, the drop in sea ice concentration is most pronounced for the ~~OSI-SAF~~ ~~OSI SAF~~ and NASA-Team algorithms. Similar to the example from 2015, the overall loss of the NSIDC product is much smaller ($40 \cdot 10^4 \text{ km}^2$) than for the other algorithms: ~~112~~ ~~10^4~~ ~~106~~ ~~$\cdot 10^4$~~ km^2 for ~~OSI-SAF~~ ~~OSI SAF~~, $120 \cdot 10^4 \text{ km}^2$ for ASI and $132 \cdot 10^4 \text{ km}^2$ for the NASA-Team algorithm. In both examples, the day of minimum sea ice concentration is consistent within the products except for the NSIDC algorithm. However, the overall sea ice concentration reduction for the NSIDC CDR is very low and thus the result are less meaningful for the NSIDC retrieval.

Figure 5. April 2020 warming wave and its influence on the three different sea ice concentration algorithms. Top panel shows the extent of the warming wave subdivided into three temperature categories (left) and the average sea ice concentration for each category for the time period between April 09 and May 09. Bottom panel (left) shows the Average air temperature for the whole influenced area (i.e., [daily max. 2 m air temperature](#) $> -10^{\circ}\text{C}$). Gray shading indicates the 10 and 90 percentiles. Row 2 - 5 show the sea ice concentration for the different retrievals for the day where their respective ice concentration for the influenced area is lowest (the minimum ice concentration is calculated for the $T > -5^{\circ}\text{C}$ category). The date is given in the figure.

260 4.2 Statistical results

In this section, we analyze the impact of all warm air intrusions detected during the 41-year period from December 1979 to April 2020. The results are shown in terms of effective area reduction caused by the influence of the [warming-eventswarm air intrusions](#). A full definition of this parameter is given in [appendixsection 3.2](#). Here we want to remind the reader that this effective area reduction is mainly due to too low retrieved sea ice concentration during (and after) [the-warming-eventstheair intrusions](#). As described in [appendixsection 3](#), best efforts have been made to exclude other effects (ice breakup, polynya opening, melting) that could lead to a natural decrease of sea ice concentration. The influence of potential natural processes that reduce the ice concentration during [a-warm air intrusions](#) are discussed in section 5.3. A full overview of all warm air intrusions detected during the 41 year period is given in Figure 6, left. Figure 6, right shows only the largest warming events (65 percentile of largest effective area [lossreduction](#)) of the [OSI-SAF-OSI SAF](#) algorithm. The individual dots represents the effective area [loss-reduction](#) due to the individual warm air intrusions for the three sea ice concentration products products (the NASA-Team algorithm is not shown since it performs similar to the [OSI-SAF-OSI SAF](#) algorithm). The black line shows the

265

270

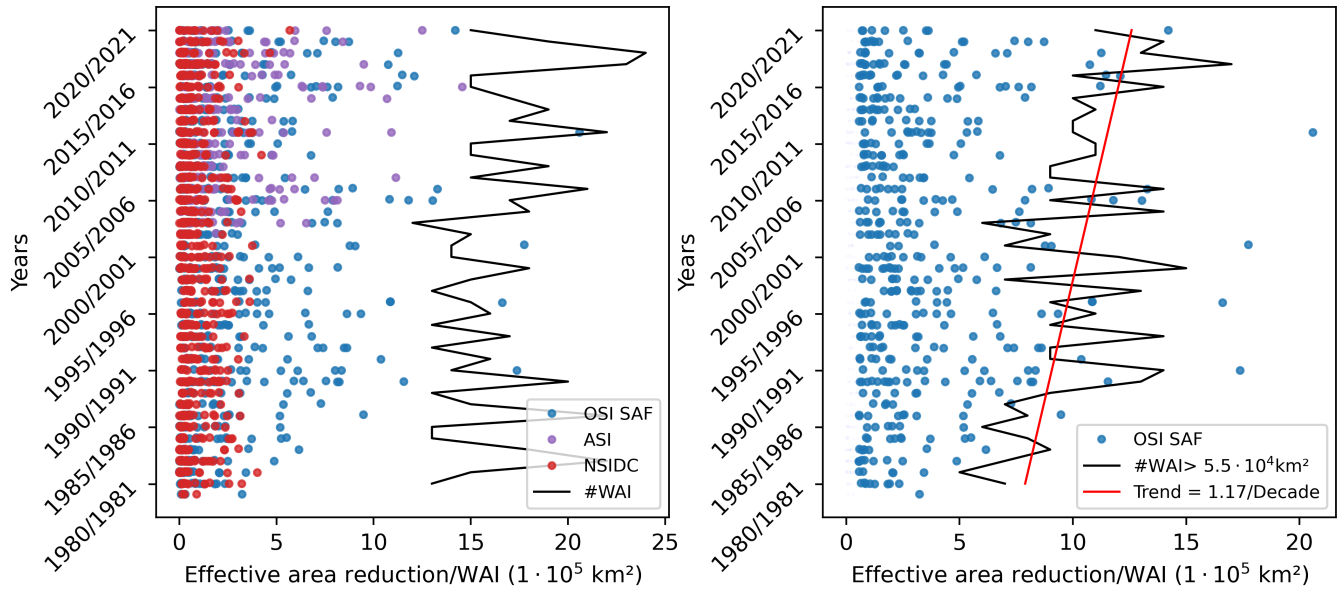

Figure 6. Left: Effective area [loss reduction](#) of the three sea ice concentration algorithms for each detected warm air intrusion in the 41-years period from November 1979 to April 2020 (the NASA-Team algorithm is not shown since it performs similar to the [OSI-SAF-OSI SAF](#) algorithm). In addition, the number of warm air intrusions (WAI) per season is shown as black line. Right: Same as left but only for large ($\geq 5.5 \cdot 10^4 > 5.5 \cdot 10^4$ km²) warm air intrusions and for the [OSI-SAF-OSI SAF](#) algorithm. In addition, the trend of # of strong warm air intrusions is given.

number (#) of warm air intrusions detected for one season. While there is only a slight increase in the number of overall events (left), there is an increasing trend (0.43 – 1.17 events/decade) of large events (right), which is, however, not significant (p value > 0.05) due to the large inter-annual variability.

275 Table 2 summarizes the average area affected by warming events for the three different categories as well as the average effective area [loss reduction](#) of the different sea ice concentration retrievals. [All categories refers to all the areas where the temperature crossed \$-10^{\circ}\text{C}\$. It is not necessarily the sum of the individual categories since the effective area reduction is calculated and optimized for every individual category.](#) In total, 723 warm air intrusions are detected. The number of warm air intrusions of category 1 and 2 are similar, roughly 100 warm air intrusions less were detected in category 3. Overall, the
 280 NSIDC CDR product performs best with very little effective area [loss reduction](#). The other three retrievals show quite similar performance. In category 1 and 2, the ASI algorithm shows a slightly stronger impact while for category 3, the NASA-Team and OSI SAF algorithms have the strongest response. In the warming detection algorithm, we additionally analyze the areas, where the warm air intrusion origin from. Over 70% of all detected waves origin from the Atlantic sector of the Arctic. Overall, small events, mainly occurring close to the ice edge in the Atlantic sector, are most frequent (not shown here).

Table 2. Statistical overview of all detected warm air intrusions. Values of averages are given in $1e+04 \text{ km}^2$

Warming strength	All categories	1 ($> -10^\circ\text{C}$)	2 ($> -5^\circ\text{C}$)	3 ($> -2^\circ\text{C}$)
Number of warm air intrusions	723	637	640	554
Average area (90 pct)	82 (197)	40 (88)	27 (61)	30 (67)
NSIDC area loss (90 pct)	8 (21)	3 (8)	3 (8)	4 (11)
OSI-SAF <u>OSI SAF</u> area loss (90 pct)	20 (56 57)	5 (13 14)	6 (19)	10 (30)11 (36)
ASI area loss (90 pct)	18 (51)	7 (17)	7 (20)	8 (23)
NASA-Team area loss (90 pct)	21 (56)	5 (16)	6 (17)	10 (26)

285 The ~~impact of the warm air intrusions on the~~ performance of the individual sea ice products is compared in Figure 7. Top left shows a boxplot diagram of the effective area reduction divided by the whole sea ice cover impacted by the warming events (%) for the three categories. For all retrievals, the impact of the warm air intrusions increases with the temperature threshold reached by the warm air intrusion. The NSIDC product is only moderately influenced by the warm air intrusions, only for the 3rd category, the average impact is above 1%. In this 3rd category, the ~~OSI-SAF~~ OSI SAF and NASA-Team algorithms show
290 the strongest impact.

Comparing the time periods from 1979 – 1990 (Figure 7, bottom left) and 2010 – 2020 (Figure 7, bottom right), the average loss is similar for the warm air intrusions of category 1. In the categories 2 and 3, an increased effective area reduction is observed in recent years for the ~~OSI-SAF~~ OSI SAF and NASA-Team algorithms, supporting the increased trend shown in Figure 6, right. For example, the mean (median) effective area reduction for the ~~OSI-SAF~~ OSI SAF retrieval for category
295 3 is 3.7 (2.6) for the early period and ~~4.1~~ 4.0 (3.6) for the late period. A similar increase is found for the NASA-Team algorithm.

Figure 7, top right shows the 41-year average of effective area ~~loss for the OSI-SAF~~ reduction for the OSI SAF algorithm for the different months from December to April. In April, the warm air intrusions of category 3 have clearly the strongest impact on the performance of the ~~OSI-SAF~~ OSI SAF algorithm, with an average monthly effective area ~~loss of 15.7~~ reduction of
300 15.8 $\cdot 10^4$. A similar pattern can be found for the other algorithms (except for NSIDC, see Figure A1). Splitting the analysis of the monthly effective area reduction to the periods 1979-1989 and 2010-2020, the effective area reduction in April for category 3 is twice as large in the later decade (Figure A2). In other months, the differences are less pronounced.

Figure 8 shows the time series of the effective area ~~loss~~ reduction during April and December for the ~~OSI-SAF~~ OSI SAF,
305 NSIDC and ASI algorithms for warm air intrusions of category 3. The NASA-Team algorithm is not shown here as it performs very similar to the ~~OSI-SAF~~ OSI SAF algorithm. Note that November, the first month of our analysis, is not shown since during this month, the impact of new forming ice and cracking of ice makes the calculation of the effective area ~~loss~~ reduction more uncertain. In April, most of the warm air intrusions with strong impact occur in the last two decades, as visible for the ~~OSI-SAF~~ OSI SAF and ASI algorithms. A similar increase of strong warm air intrusions is also found in category 2 (not
310 shown). In December, no increase in effective area reduction, but rather a period with stronger warm air intrusions between

Figure 7. Top left: Boxplot of the effective area reduction (%) of the four sea ice concentration algorithms and the three different warming classes. The boxes show the 25th and 75th percentiles. In addition the medians (black line) and 10th and 90th percentiles (whiskers) are given. Top right: Monthly distribution of the effective area reduction for the ~~OSI-SAF~~ OSI SAF algorithm (average over 41 years). Bottom: same as top left but for the winters 1979-1990 (left) and 2010-2020 (right). Note that no ASI data is available before 2002.

Figure 8. Time series of the effective area ~~loss-reduction~~ for April (top) and December (bottom) for warm air intrusions of category 3 ($> -2^{\circ}\text{C}$).

1983 and 1992 is found. After this period, only in a few individual years (e.g., [2003](#) and [2007](#)), strong category 3 waves are detected. No increase of warm air intrusions of category 2 or 3 could be found in other months (not shown). We, however, note that in January (February), almost no strong warm air intrusions of category 3 were detected before 1990 (1986) (not shown).

315 The results presented in the Figures 6 to 8 show that the strength ~~and frequency~~ of the warm air intrusions increased in the last 20 years, ~~especially most pronounced~~ during April. ~~Compared Especially the impact of warm air intrusions of category 3 strongly increased compared~~ to the earlier years between 1980 and ~~1990, 1990~~. ~~Not only did~~ the average area of category 3 ~~warm air intrusions increased from $58 \cdot 10^4$ km to $71 \cdot 10^4$ intrusions increase between the earlier (1980 to 1990 = $58 \cdot 10^4$ km in the period from) and recent years (2010 to 2020. Additionally, 2020 = $71 \cdot 10^4$ km), but also~~ the average length of these waves
 320 increased from 6 to 8 days (not shown). ~~All of these changes contribute to an increased impact of category 3 warm air intrusions on the sea ice concentration in recent years.~~

5 Discussion

5.1 Uncertainty of the warm air intrusion detection method

An accurate uncertainty estimation of the results provided in the previous ~~chapter~~ section is challenging due to the high number of unknowns. A sensitivity test suggest an uncertainty of the method itself of around 5% (see ~~Appendix~~ section 3.3). Additionally, there are several sources of uncertainty which are hard to quantify. In the following, we will give an overview of the uncertainty sources and provide a qualitative estimate of their impact if possible.

ERA5 2 m air temperature has a known ~~negative bias during cloudy and~~ a positive bias ~~during clear sky conditions~~ over Arctic sea ice (Herrmannsdörfer et al., 2023). ~~Through this bias a possible underestimation of the detected areas where a certain temperature threshold is crossed might therefore lead to an underestimation of the total effective area loss~~ (Batrak and Müller, 2019; Herrmannsdörfer et al., 2023; Wang et al., 2019). ~~Because of this bias, some warm air intrusions might be wrongly captured by the algorithm.~~ Also, miss-classification could be a result of ~~a the~~ temperature bias (e.g., ~~due to a negative bias,~~ an area which is classified as $> -105^{\circ}\text{C}$ might belong to the $> -510^{\circ}\text{C}$ class in reality).

Especially during November, sea ice can rapidly grow also during a warm air intrusion. Consequently, defining the reference period for the effective area ~~loss~~ reduction calculation (see ~~Appendix~~ section 3.2) can be challenging and is sometimes not possible. Therefore, the results presented here are limited to December - April, event though, warm air intrusions frequently occur also during November. In April, after a warm air intrusion, the air temperature can remain high until the end of the winter season (the detection stops at April 30 but additional 10 days in May are analyzed to properly define warming events occurring in the last third of April). Consequently, it is sometimes difficult to define the end of a warm air intrusion and to detect a proper reference period. These initially detected warm air intrusions were discarded in the results presented here and thus the effective area ~~loss~~ reduction in April might be underestimated.

Strong synoptic events like warm air intrusions can push and/or move the sea ice edge and, due to increased ice dynamics, can lead to the opening/and closing of leads. Leads modify the sea ice concentration derived by passive microwave algorithms and thus can influence the calculated effective area ~~loss~~ reduction. To mitigate this influence, the algorithm is only applied in areas where the sea ice concentration remains above 65% for the whole period of investigation. This is a conservative approach to ensure that there is no false detection of sea ice reduction due to the warm air intrusion but consequently the effective area reduction considering the whole sea ice covered Arctic can be expected to be higher than presented here.

5.2 Uncertainty Estimates of Satellite Sea Ice Concentration Retrievals

Both CDR ~~algorithm provide a sophisticated~~ algorithms provide an uncertainty estimation. For the ~~OSI-SAF~~ OSI SAF algorithm, the uncertainty in the central Arctic (i.e., high sea ice concentration) is usually around 2% - 3%. In areas with high ice dynamics (= high temporal variability in ice concentration), the uncertainty can increase to 5%. A similar increase in uncertainty is also visible under the effect of strong warm air intrusions (e.g., category $> -5^{\circ}\text{C}$ or higher). During strong warm air intrusions, sea ice concentration can drop by more than 10% for a substantial amount of grid cells, meaning that this drop in

SIC is not fully covered by an increase of uncertainty.

355

For example, for the two warming events discussed in detail in the results section (Figures 4 and 5) ~~in 50%~~ (Figure 4) and ~~30%~~ (Figure 5) of the area affected ($> -5^{\circ}\text{C}$, reference SIC $> 95\%$), the reduction of sea ice concentration was larger than the uncertainty estimate of the ~~OSI-SAF algorithm~~ OSI SAF algorithm (at the maximum sea ice concentration reduction). Similar results were found for warm air intrusions $> -2^{\circ}\text{C}$ in the high sea ice concentration domain. It is to note that large parts of the $> -2^{\circ}\text{C}$ warm air intrusions happen in the marginal ice zone in the intermediate sea ice cover domain ($50\% < \text{SIC} < 75\%$), here the uncertainty of the ~~OSI-SAF~~ OSI SAF algorithm is higher and often as high as the reduction in SIC due to the warm air intrusions.

The NSIDC CDR provides a quality assessment and a standard deviation to estimate the uncertainty of the sea ice concentration. The standard deviation of a grid cell is estimated from the 9 surrounding grid cells from each sub-algorithm used (NASA-Team and Bootstrap). In the central Arctic it is usually between 0% and 2% but can be 10% and higher in the marginal ice zone. As shown in Figure 7, the NSIDC CDR is overall less influenced by warm air intrusions and mainly the $> -2^{\circ}\text{C}$ warm air intrusions have an impact on the derived ice concentration. For warm air intrusions $> -2^{\circ}\text{C}$ in the high sea ice concentration domain, we find that in 25% – 40% of the cases, the sea ice reduction is higher than the uncertainty of the retrieval. It is to note that the sea ice concentration reduction of individual grid cells is rarely above 5% in the NSIDC CDR.

370 Overall, the effect of the warm air intrusions is not fully captured by the uncertainty of both CDR algorithms. An increased uncertainty needs to be considered in the case of strong warming events.

Since the NSIDC CDR is way less influenced by warm air intrusions, it is worth discussing the reason for its good performance in our study. The NSIDC CDR is computed from the NASA-Team (Cavalieri et al., 1997) and Bootstrap (Comiso, 1986) algorithms. The CDR sea ice concentration is based on the sub algorithm with the higher sea ice concentration, which, in case of strong warm air intrusions, usually is the Bootstrap algorithm (since the NASA-Team algorithm shows a strong underestimation of sea ice concentration during warm air intrusions). In the NSIDC CDR, an updated Bootstrap algorithm with dynamic (daily adapted) tie points for open ocean and full sea ice cover is used (Comiso et al., 2017). By using dynamic tie points the impact of changing snow and surface conditions are mitigated and thus the impact of warm air intrusions on the derived sea ice concentration is reduced.

380 While the NSIDC CDR generally performs best during warming events, we note that an overestimation of sea ice concentration can be a result of the method applied in this algorithm. ~~Especially in areas like the Greenland Sea, This can especially occur in areas with~~ frequent polynyas and large leads ~~open openings~~ after strong storm events. ~~These are, like for example the Greenland Sea. Such real reductions in sea ice concentration are often~~ not captured by the NSIDC CDR, while in the ~~OSI-SAF~~ OSI SAF CDR or the ASI algorithm using its natural resolution (6.25 km^2), these events are clearly visible (see Figure 9). Kern et al. (2019) performed an inter-comparison of several sea ice concentration products and found that the NSIDC CDR systematically overestimates sea ice concentration by around 3% when the ice concentration is close to 100%. This overestimation is not visible in the final product since the NSIDC CDR is truncated at 100% ice concentration. Therefore,

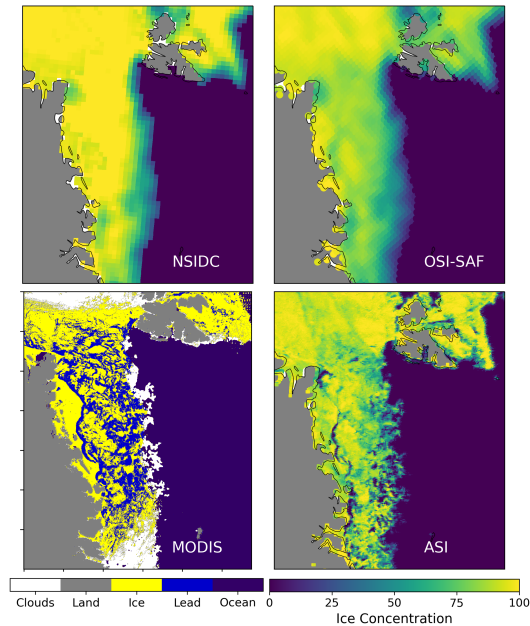

Figure 9. Sea ice concentration in the Fram Strait for 20 April 2020 for three different algorithms. In addition, sea ice leads derived from MODIS (Willmes and Heinemann, 2015) are shown.

390 in the case of strong warm air intrusions, the NSIDC CDR sea ice concentration can remain close to 100% even though the (non-truncated) ice concentration would drop by a few % (e.g., from 103% to 99%).

The results of this study show that in recent years, high impact warm air intrusions have become more frequent and their impact on satellite sea ice algorithms became stronger (Figure 8). With further Arctic warming it is likely that strong warm air intrusions will occur even more frequent and might ~~extent~~extend to earlier months in the year, although no such trend was observed, for e.g., March in this study. The associated increased uncertainty in winter time satellite derived sea ice concentration needs to be addressed. In principle, a warm air intrusion detection algorithm as presented here could be used to reprocess sea ice climatologies, "correcting" for the impact of strong warm air intrusions. However, currently the high uncertainty of this method due to, e.g., not considering leads, flagging out the marginal ice zone area, choice of the reference sea ice concentration period, make it difficult to reliably "correct" sea ice concentrations. Further improvements of this approach and additional data sets (e.g., SAR lead classification) are needed. A more simple approach could aim for including air temperature variability in the uncertainty estimation. This could help to improve the winter time uncertainty estimation, especially in the Central Arctic, where strong warm air intrusions are one of the main sources for uncertainty.

400

5.3 Sea Ice Concentration Reduction

Aue et al. (2022) analyzed the impact of cyclones on the sea ice concentration in the Atlantic sector of the Arctic ocean and
405 found an average drop in sea ice concentration of less than 2% in ± 3 days around the cyclone events. The drop in SIC was
stronger close to the ice edge and in the low ice concentration regimes. Almost no drop in sea ice concentration was found in
the central Arctic.

Table 3 shows the cases detected of warm air intrusions (%) during which the average sea ice concentration reduction is
above 2% for the three different categories. For warm air intrusions of category 2 or 3, the majority of warm air intrusions (>>
410 60%) led to a reduction of SIC >> 2% for the ~~OSI-SAF~~ OSI SAF and NASA-Team ~~algorithm~~ algorithms. In comparison, for
the NSIDC and ASI ~~algorithm~~ algorithms only about 30% of the warm air intrusions in category 2 caused a reduction of >>
2%. For category 3, almost 50% of all warming events caused a sea ice concentration reduction >> 2% for the ASI algorithm
which, however, is still well below what was found for ~~OSI-SAF~~ OSI SAF and NASA-Team (roughly 70%).

It is important to keep in mind that in this study, SIC reduction was averaged over the whole affected period which is much
415 longer (~~on average up to~~ 12 days) than the 6 days considered in the study by Aue et al. (2022). More than 5 days after the
cyclone event, Aue et al. (2022) reported a SIC increase in most of the areas in the Arctic and only an average reduction of <1%
in the Greenland Sea. Using a threshold of 1% SIC reduction in our analysis, for ~~OSI-SAF~~ OSI SAF, NASA-Team and ASI
over than 80% of the warm air intrusions (for category 2 and 3) caused an average sea ice concentration reduction above the 1%
threshold. Only the NSIDC algorithm remains below this threshold in roughly 50% of the cases. ~~An other~~ Another recent study
420 found similar effects of cyclones on the sea ice concentration (Clancy et al., 2021) leading to a reduction in ice concentration
between 1 - 3%, with strongest effects in the marginal ice zone. Graham et al. (2017) found a strong storm introduced reduction
of sea ice concentration in February 2015 north of Svalbard during the N-ICE2015 drift campaign. A detailed analysis showed
that for the February 2015 warm air intrusion (as detected with the here presented algorithm), the area around (and south of)
the campaign location was masked out since the automatic ice edge and polynya masks triggered (see Appendix section 3).
425 The remaining effected area was of medium size ($5 \cdot 10^5 \text{ km}^2$) and the sea ice reduction (e.g., 2.5% for the ~~OSI-SAF~~ OSI SAF
algorithm) was not exceptional. The Aue et al. (2022), Clancy et al. (2021), and Graham et al. (2019a) studies attribute the
changes in SIC to natural causes implied by the passing cyclone and not a deficiency of the satellite SIC products ~~used~~.

These findings demonstrate that in the majority of the warm air intrusions or cyclones, one can expect a natural and real
430 change in SIC of 1 – 3%, e.g., by opening of leads. The reduction in sea ice concentration we find for warming events (for
some algorithms > 2% SIC reduction in > 60% of the cases, see Table 3) is thus more than what would be expected due to
potential increased lead openings. This is especially true for the strong warm air intrusions, were we often found the impact of
the warming event on SIC lasting up to a week after the event.

In summary, we find that during and after warm air intrusions, the reduction of sea ice concentration by all algorithms (except
435 for the NSIDC CDR) is, in many cases, higher than what would be expected by the opening of leads due to sea ice dynamics.

Table 3. Cases of warm air intrusions during which the average sea ice concentration dropped by more than 2% for the three different temperature thresholds.

	OSI-SAF <u>OSI SAF</u>	NSIDC	NASA-Team	ASI
> -10°C	40 <u>38</u> %	11%	38%	23%
> -5°C	60 <u>62</u> %	32%	61%	30%
> -2°C	70 <u>74</u> %	34%	68%	50%

6 Conclusions

In this study, we analyzed the impact of warm air intrusions on sea ice concentration climatologies derived from microwave radiometer satellite measurements. We investigated the following questions: I) is the impact of warm air intrusions on satellite-based sea ice concentration algorithms a relevant source of uncertainty for sea ice climatologies? II) ~~In the course of Arctic amplification, do these~~ Did the recent amplified temperature increase in the Arctic led to an increase in frequency and extent of winter warm air intrusions have? Has the impact of warm air intrusions on satellite sea ice concentration algorithms increased in recent years and will they become more relevant in future?

I) Based on the results presented here (e.g., Figure 4, 5 and 7), we have shown that warm air intrusions can have a strong impact on most sea ice concentration algorithms (except the NSIDC CDR), leading to an underestimation of sea ice concentration and consequently an underestimation of sea ice area. Depending on the algorithm, this underestimation is on average between 2% to 4% of the total area affected by the warm air intrusion (Figure 7) for warm air intrusions of category 3. For large warm air intrusions (e.g., in April 2015, Figure 4), the effective sea ice area reduction is in the order of ~~75~~~~· 10⁴~~ 78 · 10⁴ km² to 115 · 10⁴ km² (~~OSI-SAF~~ OSI SAF and ASI) over the whole influenced period (9 days) and up to 19 · 10⁴ km² for a single day (ASI). During strong warm air intrusions, reduction in sea ice concentration due to the warming is often not fully captured in the uncertainty of both CDR products.

II) In general, we found that warm air intrusions of category 3 (i.e., the warmest > 2°C category) are most prominent in April (Figure 7, top right) and that in April they have an increased impact on the satellite algorithms in the last two decades (Figure 8). For the other months, no such increase is evident in the data. In the scope of a further climate change, it can be expected that such warm air intrusions will become even more frequent and that category 3 intrusions will extend further into the central Arctic.

During strong warming events the NSIDC CDR benefits from including the Bootstrap algorithm (Comiso, 1986) which ~~seems to be~~ is less sensitive to the impact of the warm air intrusions on the snow/ice system. In general, lower frequencies (e.g., 6.9 GHz) are less influenced by warm air intrusions (Rückert et al., 2023), since these are mainly short-term events and the warming rarely reaches the snow/ice interface where the low-frequency signal mainly originates. With future higher-

resolution low frequency observations (e.g., the CIMR – Copernicus Imaging Microwave Radiometer) such algorithms using lower frequencies could be used as a reference for correcting current algorithms during strong warm air intrusions.

465 *Data availability.* The NSIDC CDR and NASA-Team sea ice concentrations used in this study are available via <https://nsidc.org/data/g02202/versions/4>. The OSI SAF CDR is available via <https://OSISAF.eumetsat.int/products/osi-450-a> and the ASI ice concentration can be downloaded from https://data.seaice.uni-bremen.de/amr2/asi_daygrid_swath/n6250/. The ERA5 2 m air temperature data can be obtained from <https://cds.climate.copernicus.eu/cdsapp#!/home>. The core algorithm and an overview file of all detected warm air intrusions is available at 10.5281/zenodo.8160071

Appendix A: Warm air intrusion detection algorithm

470 1 Overview of procedure

An overview of the procedure of the algorithm to detect warm air intrusions is given in Figure 1. The input for the detection algorithm are 30-days arrays of gridded ERA-5 2 m air temperature (T2m) and OSI-SAF sea ice concentration (SIC). Based on the thresholds defined (here used: category 1: $> -10^{\circ}\text{C}$, category 2: $> -5^{\circ}\text{C}$, and category 3: $> -2^{\circ}\text{C}$), the *Threshold detection* procedure detects connected areas where the temperature thresholds are crossed for a certain amount of days (here used: 2 days). Several not connected regions can be detected and they will be merged if their borders are separated by 2 pixels (= 50 km) or less.

480 During the detection, a land mask, a polynya mask, and a dynamic ice edge mask are applied. The ice edge mask is derived from the minimum extent of SIC $> 65\%$ during the 30-day period. For the polynya mask, we analyzed 41 years of winter OSI-SAF sea ice concentration and masked out areas where the SIC frequently dropped below 50% while the ice edge was far away. Masked out areas are, e.g., Svalbard or Novaya Semlya (see Figure 2).

the *Threshold detection* interacts with the *Similarity check* procedure. Here, it is tested if the current detected warm air intrusions are similar to the previously detected ones. First, the overlapping area of the new and previous warm air intrusion is calculated. If the overlap is above 70%, the larger intrusion area is used for further calculations and the other one is discarded. If the extent of both intrusions is similar, the warm air intrusion with the larger effective area loss (see section 3.2) is used.

485 In the next step, the detected areas are combined with the sea ice concentration data sets and the procedure *Effective area reduction* is applied. In this module, the effective area reduction (see section 3.2) is calculated for each sea ice concentration data set and for each defined threshold. The data is finally stored in the *Output array*. In this study, the algorithm is applied for the winter season November – April. With a 5 day time step, in each iteration, 30 days of T2m and SIC are analyzed. A sensitivity test showed that a 5 day step is needed to ensure that the warm air intrusions is optimally captured while the processing time of a season remains reasonably short. Overview of the warm air intrusion detection algorithm. Here WAI is the abbreviation for warm air intrusions. Extended landmask used in the algorithm. Grey areas indicate the landmask and red areas indicate the area where the polynya mask is applied.

1 Effective area reduction

In order to break down the impact of the warm air intrusions on the sea ice concentration to one number, the "effective area reduction" is defined. This parameter describes the effective area reduction due to a reduction of sea ice concentration during the period impacted by a warm air intrusion in comparison to the reference sea ice concentration before and after the event. Figure 3 shows the basic principle of this calculation. Shown are the sea ice concentration and the 2 m air temperature averaged over the area where the threshold $> -5^{\circ}\text{C}$ was crossed. The whole area was around $2 \cdot 10^6 \text{ km}^2$. The reference sea ice concentration is the average SIC from the days before and after the influence of the warming event on the ice concentration. In this example, the sea ice concentration during the reference period (blue) is above 99% and drops to 95% during the warming event (red). The resulting effective area loss is $6 \cdot 10^5 \text{ km}^2$ over the whole red period (16 days) or $\approx 2\%/day$.

Defining the time period during which the sea ice concentration is affected by the warm air intrusion is not straight forward. In this study, the following procedure was chosen: The start of the affected period is based on the day, when the 2 m air temperature first crossed the $> -10^{\circ}\text{C}$ mark. The end of the period is reached when the sea ice concentration is close (within 1%) of the reference sea ice concentration from before the event. If the latter does not apply, the end of the affected period is set to 10 days after the peak of the warming.

1 Sensitivity check

We note that the calculated effective area loss is depending on the choice of parameters (reference periods, affected period, iteration step length). We performed a sensitivity study varying the controlling parameters for five test warm air intrusions to estimate their impact on the effective area loss. In the example given in Figure 3, varying the start and end dates for the affected period (red line) by ± 2 days would lead to changes in effective area loss of around 5%. Varying the selection of the reference period in a similar way led to changes of around 3%. Reducing the iteration step to 1 day instead of 5 days to find the optimal window for the warm air intrusions did not lead to relevant changes for the example shown above. Analyzing 5 selected large warm air intrusions (March 1990, December 2016, April 2015 and 2020, and February 2020), on average, the effective area loss varied by $\pm 6\%$ due to varying the reference periods and affected periods as described above. In two cases, optimizing the warm air intrusion detection by using an iteration step length of 1 day increased the effective area loss by more than 3% and 7%, respectively. For the other cases, no relevant changes were observed. Concluding, an uncertainty in effective area loss of roughly 5% can be expected introduced by using fixed parameters for the warm air intrusion detection. Example for the effective area loss calculation. The sea ice concentration is an average over the whole area affected by the warm air intrusion (around $2 \cdot 10^6 \text{ km}^2$). Gray shading indicate the 15 and 85 percentiles of the 2 m air temperature.

Sea ice concentration in the Fram Strait for 20 April 2020 for three different algorithms. In addition, sea ice leads derived from MODIS (Willmes and Heinemann, 2015) are shown.

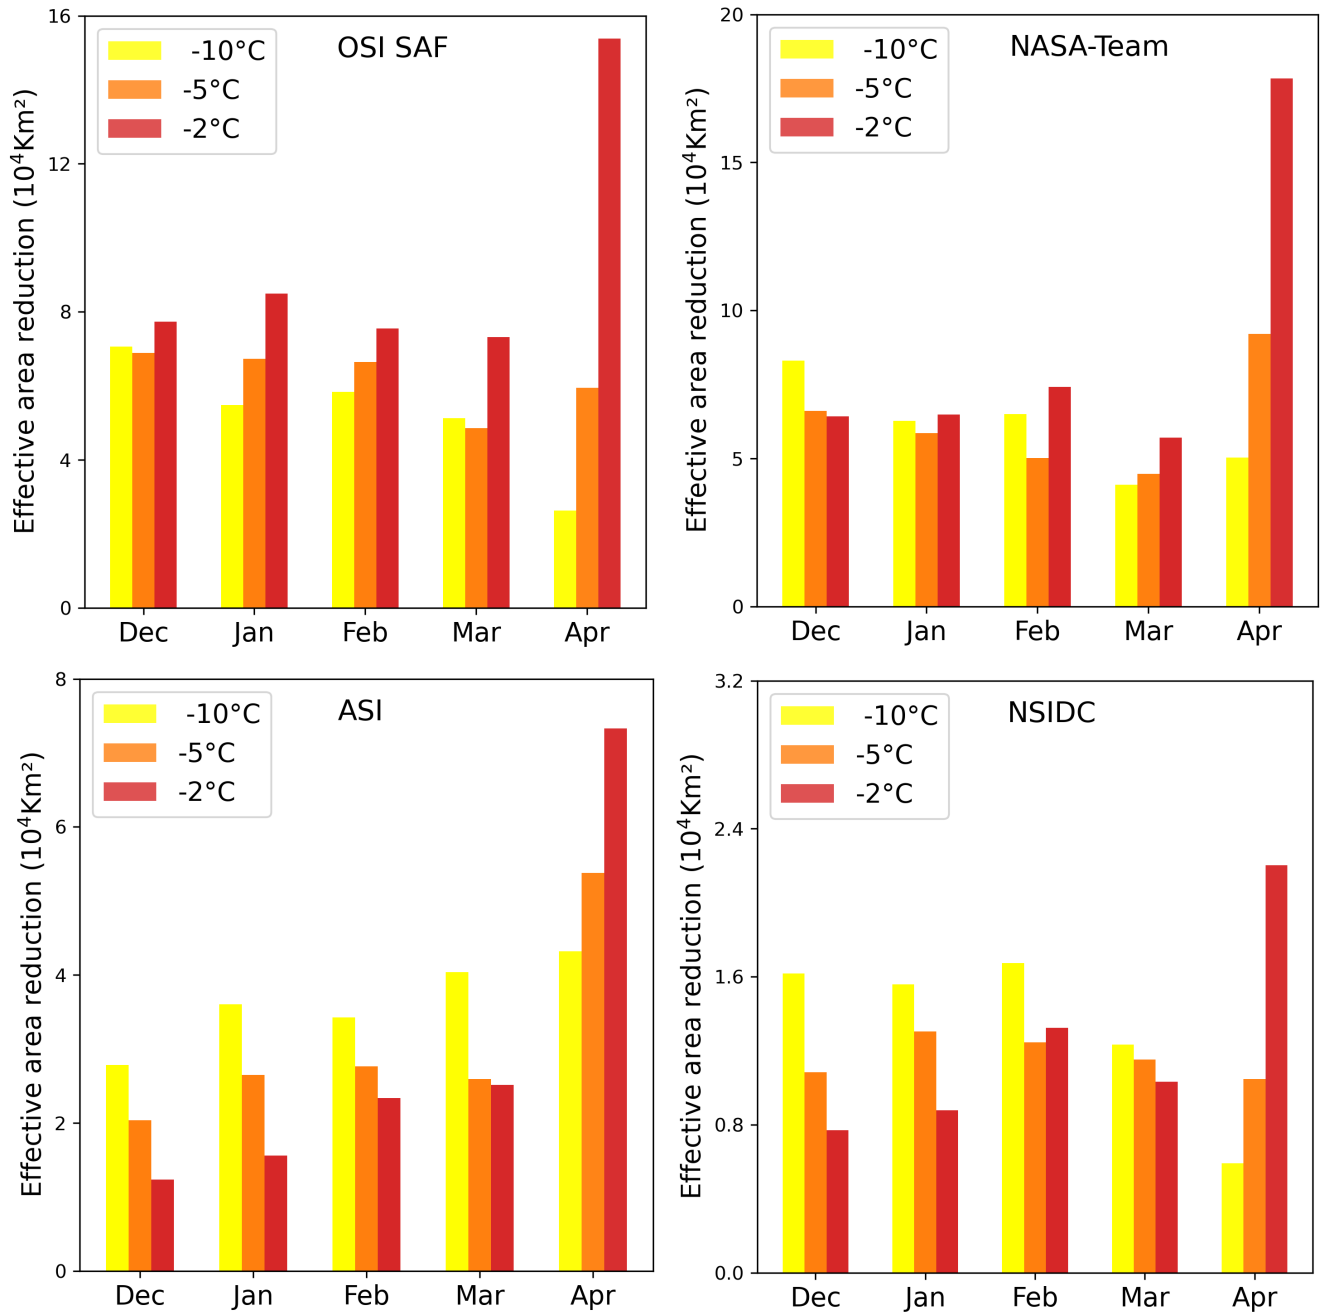

Figure A1. Monthly distribution of the effective area reduction for the four different algorithms (average over 41 years). [Note that the scale of the y-axis is different for each panel.](#)

Figure A2. Monthly distribution of the effective area reduction for the ~~OSI-SAF~~ OSI SAF algorithm for the years 1979-1990 and 2009-2020 and for warm air intrusions of category 3 (i.e., daily max. 2 m temperature > -2°C).

Author contributions. PR performed the study and wrote the initial version of the article. GS contributed to the discussion and development of the study. All authors revised and commented on the article.
