Abstract. Meltwater plume deposits (MPDs) from marine sediment cores have elucidated clearly connected, yet difficult to constrain, relationships between ice-marginal landform construction, grounding-zone retreat patterns, and subglacial hydrology for several glacial systems in both hemispheres. Few attempts have been made, however, to infer coveted details of subglacial hydrology, such as flow regime, drainage style, and mode(s) of sediment transport through time from grain-scale characteristics of MPDs. Using MPD, till, and ice-proximal diamicton samples collected offshore of six modern and relict glacial systems in both hemispheres, we examine whether grain-shape distributions and microtexture assemblages (collectively, grain micromorphology) of the silt fraction are the result of subglacial meltwater action, or are indistinguishable from glacial proximal and subglacial sediments from the same region. We find that of all grains imaged (n=9,400), three-quarters can be described by one-quarter of the full range of measured shape morphometrics, indicating widespread and efficient abrasive processes in subglacial environments. Microtexture analysis reveals that while grains comprising MPDs show evidence of edge rounding more often than tills, fluvial microtextures occur in modest amounts on grain surfaces. Furthermore, MPDs retain many mechanical (i.e., glacial) textures in comparable abundances to tills. Significant alteration of MPDs from till sources is observed for systems (1) for which intensive, potentially catastrophic, meltwater drainage events in the Holocene are inferred from marine geologic records, and (2) with comparatively less mature till grains and a contribution of supraglacial melt to the bed, indicating that quantifiable grain-shape alteration of MPDs may reflect a combination of young till, high-energy flow of subglacial meltwater, persistent sediment entrainment, and/or long sediment transport distances. We encourage future works to integrate grain micromorphology into site-specific marine sediment analyses, which may distinguish
periods of persistent, well-connected subglacial discharge from periods of sporadic or disorganized drainage and provide context needed to estimate sediment fluxes and characterize ice response to subglacial meltwater transmission. In addition, this work demonstrates that glacial and fluvial surface textures are retained on silts in adequate abundance for microtexture analysis.

1 Introduction

The distribution and transmission of water beneath ice sheets influences subglacial sediment deformation (Alley et al., 1986; Boulton et al., 2001; Iverson, 2010) and, subsequently, ice-flow dynamics (e.g., Stearns et al., 2008; Gustafson et al., 2022; Livingstone et al., 2022 and references therein). As quantities of ice sheet surface melt production and drainage to the ice sheet bed are modeled to increase in coming decades (Trusel et al., 2015; Lenaerts et al., 2016; Flowers, 2018; Gilbert and Kittel, 2021), continued efforts towards a nuanced understanding of subglacial hydrology at all scales is needed. Marine sediment cores collected from deglaciated continental shelves record discrete meltwater drainage events and persistence of subglacial drainage pathways with temporal resolutions of centuries to millennia (Witus et al., 2014; Prothro et al., 2018; O’Regan et al., 2021; Jennings et al., 2022; Lepp et al., 2022). Numerous marine sediment cores collected offshore of extant continental ice sheets have recovered distinctive meltwater plume deposits (MPDs) that, upon integration into glaciomarine facies models and bathymetric observations, have revealed connections between subglacial hydrologic activity and ice-marginal behavior prior to and during glacial retreat (Simkins et al., 2017; Prothro et al., 2018; O’Regan et al., 2021). However, very little work has been done to infer pertinent details of paleo-subglacial hydrology, such as evolution of drainage pathways or sediment mobilization within subglacial meltwater flow, using subglacially-sourced MPDs.

Research characterizing MPDs has largely relied on grain size (Witus et al., 2014; Simkins et al., 2017; Prothro et al., 2018, 2020), magnetic susceptibility (Witus et al., 2014; Smith et al., 2017), stratigraphy (O’Regan et al., 2021; Lepp et al., 2022; Lešić et al., 2022; Jennings et al., 2022; Clark et al., 2023), and water content (Streuff et al., 2017; Lepp et al., 2022; Clark et al., 2023). In acoustic data, sediments comprising MPDs appear stratified and drape the seafloor topography (Witus et al., 2014; Hogan et al., 2020; Jennings et al., 2022; Lepp et al., 2022; Roseby et al., 2022) reflective of suspension settling, and may infill bathymetric lows or basins (e.g., Nitsche et al., 2013; Witus et al., 2014; Roseby et al., 2022). In sediment cores, MPDs are often laminated or thinly bedded, where subtle variation in grain size between laminae may be indicative of varying plume dynamics, magnitude, or proximity of the ice margin (Ó Cofaigh and Dowdeswell, 2001; O’Regan et al., 2021; Jennings et al., 2022; Lepp et al., 2022; Roseby et al., 2022). Shared grain size modes (Simkins et al., 2017; Prothro et al., 2018), and more recently geochemical similarities (Lepp et al., 2022), between tills, ice-proximal deposits, and MPDs from the same region reflect a common subglacial origin. Furthermore, the grain-size distributions of MPDs collected offshore several Antarctic glacial systems are strikingly similar despite regional variations in subglacial geology (Halberstadt et al., 2016; Simkins et al., 2017; Prothro et al., 2018; Lepp et al., 2022), suggesting the glacial and/or glaciofluvial processes that produce these distinctive sedimentary deposits operate on an ice-sheet scale. The aforementioned processes, however, are poorly
understood and hypothesized mechanisms for subglacial mobilization and sorting of MPDs observed offshore (e.g., Schroeder et al., 2019) have not been empirically evaluated.

Grain shape is considered to be a cumulative function of bedrock geology, effects of weathering on preexisting sediments, and sediment transport mechanisms (Mahaney, 2002) and is a powerful proxy for inferring sediment transport history and depositional setting (e.g., Oakey et al., 2005; Campaña et al., 2016; van Hateren et al., 2020), but has been underused in studies that characterize glacial deposits. Of those sparse works, many employ Fourier grain-shape analysis to identify harmonic ranges describing grain elongation, roughness, and transport history (Wellner et al., 2011; Livsey et al., 2013; Witus et al., 2014; Charpentier et al., 2017; Robinson et al., 2021; Clark et al., 2023). In Pine Island Bay, West Antarctica, differences in grain elongation values were calculated between tills and meltwater deposits with even though little variation in grain roughness existed (Witus et al., 2014), providing support for the use of grain shape as an indicator of subglacial sediment transport in glaciomarine environments. Complementary to grain shape, grain microtextures have been more widely examined on glaciogenic grains (Mahaney, 2002; Vos et al., 2014). Suites of microtexture assemblages are associated with different geneses, and have been useful in distinguishing sources of ice-rafted debris (Immonen, 2013; St. John et al., 2015; Passchier et al., 2021), inferring relative ice volume on glacial-interglacial timescales (Cowan et al., 2008), and evaluating distance of proglacial transport (Sweet and Brannan, 2016; Křížek et al., 2017). A micromorphologic (i.e., grain shape and microtexture) approach to examine MPDs and the tills from which they are sourced thus has the potential to reveal process-based details of hydraulic transport and grain-size production in subglacial environments.

This study combines a quantitative and qualitative approach to characterize grain micromorphology (encompassing grain shape and microtexture) of MPDs and tills, or ice-proximal diamictons, from six glaciated and formerly glaciated settings in both hemispheres: Ryder Glacier, Thor Iversenbanken, Marguerite Trough, Pine Island Glacier, Thwaites Glacier, and the Ross Sea (Fig. 1). We aim to determine whether MPDs have diagnostic grain-shape distributions and microtexture assemblages and to explore how grain-shape alteration of MPDs from their source materials may record details of subglacial sediment transport and subglacial plumbing through time.

1.1 Bathymetric and glaciological settings of study sites

Ryder Glacier drains from the northwestern Greenland Ice Sheet into the Lincoln Sea through the Sherard Osborn Fjord (O’Regan et al., 2021). Cores sampled for this study were recovered from an along-fjord transect at sites ranging in water depths from 238 m to 633 m (Table A1). Cores from the shallowest water depths (RYDER19-8PC and RYDER19-9PC) were collected atop a prominent bathymetric sill lying close to the modern ice tongue calving line (O’Regan et al., 2021). Glaciomarine sediments derive from both clastic and carbonate sedimentary sources (Henriksen et al., 2009; O’Regan et al., 2021). Early Holocene retreat of Ryder Glacier from the fjord mouth, as well as late Holocene retreat following a glacial readvance, coincide with periods of relatively warm Arctic air temperatures (Levcavalier et al., 2017; O’Regan et al., 2021).
Cores from Thor Iversenbanken in the central Barents Sea were collected from a bathymetric region featuring interconnected basins and channels (Esteves et al., 2022) approximately 15 km from the flow path of the Sentralbankrenna paleo-ice stream (Bjarnadóttir et al., 2014, Esteves et al., 2017). This basin-channel system is interpreted as a series of paleo-subglacial lake basins located beneath non-streaming ice (Esteves et al., 2022), and sedimentological analyses of cores from this region provide evidence for active subglacial drainage between basins (Esteves et al., 2022). The cores included in our study, CAGE-15-5-1221 and CAGE-15-5-1222, were recovered from an adjacent bank area and from within the lower-most basin, respectively (Esteves et al., 2022). Deglaciation of the central Barents Sea is constrained to the late Pleistocene (e.g., Winsborrow et al., 2010). The relict Barents Sea Ice Sheet is heralded as a good analog for the West Antarctic Ice Sheet, due in part to similarities in size and sedimentary subglacial geology (Andreassen and Winsborrow, 2009).

The relict Marguerite Trough Ice Stream drained the Antarctic Peninsula Ice Sheet, extending nearly 400 km from the modern coastline to the continental shelf break during the Last Glacial Maximum (LGM; Ó Cofaigh et al., 2014). Geomorphic evidence of ice streaming and a network of channels and remarkably deep (900 m) basins is preserved on the deglaciated continental shelf (Ó Cofaigh et al., 2005; Anderson and Fretwell, 2008; Livingstone et al., 2013). Cores in this study were recovered from within moderately deep basins (Table A1) to the west of George VI Trough (Kennedy and Anderson, 1989). The tills sampled for this study are composed primarily of metamorphic rock fragments and quartz, while the MPDs are rich in silt-sized quartz and feldspar grains (Kennedy and Anderson, 1989). While sediment cores recovered from Marguerite Bay often contain thick units of diatomaceous and organic-rich sediments, the MPD samples in this study were taken from units where siliceous microfossils and organic materials were virtually absent (Kennedy and Anderson, 1989). Initial retreat of the Marguerite Trough Ice Stream occurred coeval with meltwater pulse 1a approximately 14 thousand years (ka) before present (Kilfeather et al., 2011).

Thwaites and Pine Island glaciers drain into the eastern Amundsen Sea Embayment and, during the LGM, coalesced, reaching the outer continental shelf (Kirshner et al., 2012; Larter et al., 2014 and references therein). Retreat across Pine Island Bay initiated during the late Pleistocene and continued in distinct stages until the grounding lines for Pine Island and Thwaites glaciers largely stabilized within ~100 km of their current positions by ~10 ka ago. (Hillenbrand et al., 2013; Nitsche et al., 2013; Witus et al., 2014; Lepp et al., 2022). Cores used in this study (Table A1) were collected on the mid- and inner shelf from a variety of bathymetric settings, including atop an ice-proximal bathymetric high and on a ridge beneath the Pine Island Ice Shelf (Smith et al., 2017). Volcanic and plutonic rocks, largely felsic in composition, underlie the Pine Island and Thwaites glaciers (Smith et al., 2013; Schroeder et al., 2014; Simões Pereira et al., 2020), and large sedimentary basins upstream have been identified by aeromagnetic surveys (e.g., Muto et al., 2016) and inferred by observations of kaolinite-rich sediments offshore (Hillenbrand et al., 2003; Ehrmann et al., 2011; Simões Pereira et al., 2020). Geothermal heat flux is elevated in the region (Damiani et al., 2014; Schroeder et al., 2014; Dziadek et al., 2021).

Cores collected from the western Ross Sea were recovered from bank tops (NBP1502 KC22; Halberstadt et al., 2018) and from topsets and toes of grounding-zone wedges (NBP1502 KC17, KC19; Prothro et al., 2018) in water depths ranging from 354-549 m (Table A1). At the LGM, the East Antarctic Ice Sheet occupied the western Ross Sea (e.g., Anderson et al.,
however, unlike other glacial systems described, landforms on the seafloor indicate that grounded ice did not extend to the continental shelf margin (Greenwood et al., 2012; Halberstadt et al., 2016). High geothermal heat flux is inferred in the western Ross Sea (Simkins et al., 2017) based on the proximity of core sites to volcanic seamounts (Rilling et al., 2009), a rifting zone (Cooper et al., 1987), and measurements (Blackman et al., 1987 and references therein). Tills from this region are composed largely of felsic lithic fragments (Licht et al., 2005).

2 Materials and Methods

A total of 49 sediment samples from MPDs, tills, and ice-proximal glaciomarine diamictons from the regions described in Section 1.1 were gathered for grain-shape analysis (Figure 1; Table A1). For glacial systems from which subglacial till was not available (e.g., Thwaites Glacier), MPD grains were compared directly to ice-proximal diamicton grains. Other
systems from which both subglacial till and ice-proximal diamicton were available (e.g., Pine Island Glacier) compared MPD grains against all diamicton grains, merging grains from both till and ice-proximal deposits. While subglacial till and ice-proximal diamicton differ in their depositional environments and processes, the sediment transport processes responsible for grain-shape alteration are largely the same and are distinctly different from sediment transport via subglacial meltwater; therefore, incorporating materials from both subglacial till and ice-proximal diamicton in comparison against MPDs is appropriate to address the goals of this study.

In addition, sediments from basal ice recovered from Siple Dome in the Ross Sea drainage sector of West Antarctica, fringe debris (i.e., sediment entrained into basal ice through infiltration of ice into sediment pore spaces; Rempel, 2008; Meyer et al., 2019) from Pope Glacier in the Amundsen Sea drainage sector of West Antarctica, and supraglacial cryoconite debris from Qaanaaq Glacier in Northwest Greenland, underwent the same suite of analyses and are used to contextualize the micromorphologies observed in our primary sample populations (Table A1).

2.1 Grain-shape analysis

Bulk sediment samples were treated with sodium metaphosphate to deflocculate clays for 48 hours prior to analysis. Tills, ice-proximal diamictons, and basal ice debris were sieved at 500 microns (µm) to isolate matrix material. Cryoconite samples were treated with H₂O₂ to remove organics. Aliquots of sediment from a homogenized slurry were introduced into a Bettersizer S3 Plus sampling reservoir where grain size was measured through laser diffraction. Thousands of images of grains from the same aliquot were subsequently captured using the integrated microscope charge-coupled device camera. Images captured with the 10x objective were exported for shape analysis because this magnification preferentially captures finer grain sizes, including the silt-sized range prevalent in MPDs, than the 0.5x objective. The lower detection limit for the 10x objective is 0.8 µm; to avoid sampling bias skewed towards that threshold or towards clay minerals, images of grains finer than 2.4 µm were excluded from analysis (Crompton et al., 2019).

A MATLAB script for grain-shape analysis (see Data Availability section) randomly selected 200 unique images from each sample, processed images to distinguish foreground from background, converted images from grayscale to binary, and calculated three dimensionless metrics on the binarized shapes using the “regionprops” function (Fig. 2). The metrics considered include eccentricity, circularity, and solidity, and collectively provide information about grain form (i.e., roundness) and shape (regularity). Evaluating distinct shape metrics, rather than harmonic ranges or grain roughness as employed by studies referenced above, allows us to consider the magnitude of variability for each parameter within the context of the other measurements. To test the null hypothesis that grain shapes found in meltwater deposits and subglacial/ice-proximal diamictons from the same glacial systems are indistinguishable, we performed a two-type Z-test on the means of each group for each shape metric considered (probability p < 0.05). We calculate 95% confidence intervals from 1,000 bootstrap replicates for those samples and metrics showing statistically significant differences in means.
2.2 Microtexture analysis

Based on the quantitative grain shape output, a subset of samples was imaged by a scanning electron microscope (SEM) for microtexture analysis. An aliquot of the deflocculated sample was pipetted from a homogenized slurry and dispensed onto a 63 µm sieve, where a fraction that passed through was collected onto a piece of weigh paper. Once dried, a section of the weigh paper was mounted, sputter coated (Au-Pd), and imaged using an FEI Quanta 650 field-emission gun in high vacuum mode. Grain composition was verified as quartz through the Oxford AZtec energy dispersive x-ray spectrometer (EDS) program prior to imaging.

Grains were categorized by relief (high to low, following Mahaney, 2002) and roundness (angular to rounded, after Vos et al., 2014). Presence or absence of a suite of microtextures associated with glacial transport (cf. Passchier et al., 2021) and fluvial environments (cf. Vos et al., 2014; Křížek et al., 2017) were identified and calculated for each sample (Fig. 3). Percent overrepresentation is calculated as the difference between mean frequencies of occurrence by sample type for each texture. Microtexture identification primarily followed Mahaney (2002), yet because this canonical reference focuses on the sand fraction, textures on some grains were counted based on appearance rather than the specified scale. For example, Mahaney (2002) specifies arcuate and straight steps occur on the >5 µm scale, while we observed this feature on finer scales (Fig. 3).
and Ross Sea, distributions of grain eccentricity are strikingly similar with interquartile ranges from 0.38 to 0.66 for both grain populations (Fig. 4), though the median eccentricity for Thwaites Glacier grains is slightly elevated at 0.53. Marguerite Trough

Figure 3. Microtextures observed on quartz grains in the <63 µm size fraction (silt) from select till and meltwater plume deposit samples. Orange scale bar = 20 µm. Green scale bar = 5 µm. (a) Grain relief and (b) grain shape, following Mahaney (2002) and Vos et al. (2014), respectively. (c) Edge characteristics. (d) Fracture types characteristic of glacial transport, following grain types B-D from Passchier et al. (2021). Note the differences in scale bars. (e) Microtextures associated with fluvial transport, following Krížek et al. (2017). as = arcuate steps, b = breakage block, bc = breakage concavity, bp = broken plates, cf = conchoidal fracture, ea = edge abrasion, er = rounded edges, es = sharp edges, f = fracture face, ip = impact pit, lf = linear fracture, mr = meandering ridges, slf = sublinear fracture, ss = straight steps, up = upturned plates, v = v-shaped percussions.
Ice Stream is the only system where eccentricities of MPD and till grains are highly significantly different, reflecting MPD grains that are notably less elongate compared to their source material. Eccentricity of MPD and till grains from Pine Island Glacier were determined to be significantly different, again with MPD grains being less elongate (Table A2).

On average, the most circular grains are found in Ross Sea MPDs (mean: 0.63, median: 0.64) while the least circular grains are found in tills from the Thor Iversenbanken (mean: 0.55, median: 0.56). The median circularity of MPD grains is higher compared to tills for all six systems, but differences in means are statistically significant only for Ryder Glacier, Pine Island Glacier, and Ross Sea samples (Fig. 4). Interestingly, interquartile ranges for MPDs from Marguerite Trough Ice Stream and Thwaites Glacier do not show enhanced circularity relative to source material. Instead, compared to their respective source populations, these MPDs appear to have restricted subsets of circularities with similar medians as their corresponding till samples. An intercomparison of MPDs from all systems, with the addition of plume deposits from three systems with no till counterparts, reveals modest variability between interquartile range for all MPDs (0.51-0.69) with no clear regional trend (Fig. 5). MPDs from Marguerite Trough are less circular than other Antarctic deposits and have interquartile ranges very similar to those samples from the Barents Sea (Thor Iversenbanken and Kveithola) and the Nares Ice Stream. Ryder Glacier and Petermann Ice Stream MPDs have the widest interquartile ranges with median values similar to samples from PIG and the Ross Sea, respectively. Some regional differences in circularity, like in NW Greenland where glaciers have similar catchment areas and meltwater sources (Figs. 1, 5), likely reflect varied mineralogy: Petermann Glacier detritus is higher in calcite and dolomite (Jennings et al.,...
2022), Nares Ice Stream detritus in quartz and micas (Jennings et al., 2022), while Ryder Glacier detritus consists of both carbonate and clastic sedimentary materials (O’Regan et al., 2021) and shows an interquartile range of grain circularity between the other two. Yet, NW Greenland MPDs have similar distributions of grain circularity to West Antarctica MPDs (Fig. 5) and Ryder Glacier tills are more irregular than West Antarctic tills (Fig. 4), alluding to impacts on MPD grain shape unrelated to source geology. We also note that the circularity distributions for MPDs from all systems overlap with one another and are largely confined between values of 0.4 and 0.8 (Fig. 5).

Solidity describes regularity of grain perimeters, and the interquartile ranges for Ryder Glacier, Thor Iversenbanken, Pine Island Glacier, and the Ross Sea demonstrate shifts to enhanced grain regularity from tills to MPDs, with highly statistically significant differences for all but the Thor Iversenbanken (Fig. 4). As with circularity, MPD grains from Marguerite Trough and Thwaites Glacier exhibit a narrower interquartile range of solidities than is found in corresponding till samples; the mean and median distribution for each grain population is virtually the same for these systems. The median solidity for tills from Ryder Glacier, Thor Iversenbanken, and Marguerite Trough is all 0.61, while those from Pine Island Glacier, Thwaites Glacier, and the Ross Sea are slightly higher (0.628-0.634).

We acknowledge that grain size, and therefore image resolution (Fig. 2), may have some influence on the observed grain-shape distributions. However, none of the distributions for any metric considered are strongly skewed towards upper or lower limits as we would expect if image resolution were controlling the distribution of shape values. These results suggest that the preventative measures integrated into the methodology (removing grains below 2.4 µm; random selection of grains to use in analysis) sufficiently removed any grain-size bias from the quantitative grain-shape results.

### 3.2 Microtexture observations

A total of 132 grains were imaged from four MPDs and four tills/ice-proximal diamicton (Table A1). Imaging was attempted on approximately twice that number of samples, however the fine-grained and electrostatic nature of MPDs presented challenges in isolating quartz grains in the silt fraction, and many samples imaged were dominated by clays and had fewer than 10 quartz grains. The eight samples included in microtexture observations imaged between 12 and 20 quartz grains, which is within the range considered to be representative for any given SEM sample (cf. Vos et al., 2014).
We observe suites of microtextures characteristic of glacial transport on quartz grains at the micron to sub-micron scale (e.g., Fig. 3d) in both till and MPD populations, indicating microtexture analysis on glaciogenic silts is both feasible and results in meaningful data. Angular grains and grains with high relief are found to be overrepresented in till samples compared to MPDs by 31% and 10%, respectively (Fig. 6). Conversely, grains with subangular and subrounded shape, as well as low relief grains, occur in higher abundance in MPDs (Fig. 6). Round grains are comparably rare in till and MPD samples, and grains with medium relief are the most abundant relief type in both sample populations (Fig. 6). All step and fracture textures that are attributed to high stress, grinding, plucking, and abrasion in glacial environments (Vos et al., 2014; Passchier et al., 2021) are overrepresented in till grains, ranging from 3% (sawtooth fractures) to 18% (straight steps) more common than in MPDs (Fig. 6). Additionally, breakage features including blocks, concavities, and plates are observed in moderate (≤50%) abundance in both grain types and are largely overrepresented in tills.

Fluvial microtextures imparted to grain surfaces through intergranular collisions during transport in suspension are observed on both till and MPD grains, but with abundances ≤25% are not pervasive features. V-shaped percussion cracks and impact pits are overrepresented in MPD grains by only 5% and 2%, respectively, while meandering ridges are, somewhat surprisingly, overrepresented in till/ice-proximal diamicton grains by 4%. Notably, grains in MPDs exhibit edge rounding 26% more often than is observed in till and ice-proximal diamicton samples. It is important to note that, while differences in average frequencies allow us to compare microtexture abundance between tills and MPDs, nearly all textures are observed in some abundance in both populations. In other words, overrepresentation of a suite of textures in one grain type does not reflect absence, or even low abundance, of that feature in the other grain type. Edge abrasion and linear fractures, for example, are both overrepresented in till grains, but are seen on over 50% of grains in both populations.

4 Discussion

We find that quantifiable, significant differences in grain shape exist between MPDs and tills in some regions, as well as between MPDs from different regions, and that those differences can be both quantified using an automated imaging approach and, generally, verified qualitatively with microscopy. Here, we consider potential reasons for those variations and discuss implications for subglacial sediment transport processes, with an emphasis on subglacial hydrology.

4.1 Widespread subglacial sediment transport processes

Despite the variation in subglacial lithology, catchment size, glacial histories, and source(s) of basal meltwater for the glacial systems considered (Fig. 1), we find that three-quarters of all grains studied can be described by approximately one-quarter of possible grain morphologies, alluding to highly efficient and ubiquitous erosive processes that likely operate on catchment-wide scales. Through these processes, grains with extreme morphometries (i.e., highly elongated/rounded, or highly irregular/regular) are either not produced in abundance or such extremes are short-lived. Variability between glacial systems likely reflects differences in regional substrate geology and mineralogy, glacial history (i.e., textural maturity of sediments), distance of transport, volume of meltwater present, or some combination of those factors (Fig. 1). If regional geological and
mineralogical variability were driving differences in grain shape distributions, it is likely that would manifest most clearly in eccentricity because this metric could capture relative proportions of equant and elongated or platy minerals (e.g., Marsaglia et al., 2013). Yet, median eccentricity for all MPD grains varies by only ~8% between systems (Fig. 4), suggesting geological differences do not fully explain all variation in the dataset. Additionally, no distinctive grain-shape populations emerge that separate (predominately) hard bed from soft bed systems (Fig. 1), further implying that source material alone does not explain

Figure 6. Overrepresentation and frequency of occurrence of microtextures in both grain populations observed on 132 quartz grains. Refer to Fig. 3 for examples of microtextures. Angular grains and all fracture types, as well as edge abrasion, are overrepresented in till grains, whereas MPDs exhibit a higher proportion of subangular and subrounded grains with edge rounding. Many mechanical microtextures (e.g., fracture faces, linear and sublinear fractures) are observed at comparable frequencies in both grain populations.
the minor intrasystem variance. When we consider the shape distributions for supraglacial debris, basal ice debris, and basal fringe debris in relation to tills and MPDs from those regions, the erosive power of subglacial sediment transport becomes abundantly clear (Fig. 7).

Circularity of cryoconite grains from Qaanaaq Glacier, NW Greenland, and basal ice debris from Siple Dome, West Antarctica, is highly significantly different (Z >> 3.0) from grain circularity of tills recovered from nearby glacial systems. Consistent with microtexture observations (Mahaney, 2002; Cowan et al., 2008), our results suggest that englacial transport minimally influences grain shape and that elongated grains introduced to the till column from basal ice (Fig. 7b) are not preserved in abundance. Supraglacial debris contains grains with markedly different morphology than grains which have been altered in the subglacial

Figure 7. Visualization of grain shape evolution. (a), (c), and (e) show grain circularity for supra- or englacial reference material in comparison to glacial-marine diamicton, till, and meltwater plume deposits from a neighboring glacial system. SEM images of (b) cryoconite, (d) basal fringe debris, and (f) basal ice debris show highly fractured and elongated grains that are less common following subglacial transport. Note that in (c) the middle violin includes samples from ice-proximal diamicton from offshore Pine Island and Thwaites glaciers, as well as subglacial till samples from Pine Island Glacier (Table A1). Scale bar in (b), (d), and (f) is 20 microns.
environment (Fig. 7a). Less pronounced alteration is observed between grains from “dirty ice” of Kay Peak, Pope Glacier and those tills and ice-proximal diamictons in the eastern Amundsen Sea (Thwaites and Pine Island glaciers; Fig. 7c, d).

Sediment entrainment, transport, and release from the ice fringe depends on the thermal and pressure conditions of basal ice (Rempel, 2008; Iverson et al., 2017) and is, therefore, spatiotemporally transient in nature. It logically follows that differences in grain circularity are more pronounced between till and basal ice debris or cryoconite grains than between till and fringe debris, because the latter has likely undergone transport processes at the ice-bed interface prior to fringe entrainment. In the Ross Sea, a clear grain-shape continuum emerges from basal ice debris, ice-proximal diamicton, subglacial till, and MPDs where interquartile ranges incrementally shift towards higher abundance of circular grains (Fig. 7e). The intermediate grain characteristics implied within glacial-marine diamicton samples likely reflect inclusion of till pellets (Domack et al., 1999; Cowan et al., 2012; Prothro et al., 2018; Robinson et al., 2021) from basal ice into ice-marginal or gravity flow deposits. The differences we see between MPDs and till sources are more subtle than those between tills and basal ice debris, with the exception of Ryder Glacier (discussed in more detail in the next section).

The added context gleaned from supra- and englacial grain micromorphology indicates that all MPD, till, and diamicton grains in this study experienced alteration through subglacial sediment transport processes, like grain rotation and grinding, that occur predominantly in dilatant, deforming tills (Evans et al., 2006; Robinson et al., 2021). Such tills are associated with high basal water pressures and streaming of glacial ice (e.g., Boulton et al., 2001; Evans et al., 2005; Reinardy et al., 2011; Rüther et al., 2012). Thus, this finding suggests most grains experienced some degree of transport and alteration beneath fast-flowing ice, i.e., conditions that were also inferred from other paleo-subglacial records, such as subglacial bedforms and till properties, in the studied regions (Nitsche et al., 2013; Esteves et al., 2017; Jakobsson et al., 2018; Munoz and Wellner, 2018; Simkins et al., 2018; Kirkham et al., 2019, 2020; Hogan et al., 2022). No geomorphic evidence of ice streaming exists on Thor Iversenbanken (Esteves et al., 2022), however, and sediment grains from this area may have experienced morphological alteration through shearing or brittle deformation (e.g., Evans et al., 2006) that produced a slightly more irregular, elongate shape signature (Fig. 4).

The general homogeneity in grain morphology we observe may reflect the lasting impact of grain cushioning, whereby fines fill interstitial spaces between larger till clasts and, through grain rolling, act to absorb and dissipate tensile stresses along grain bridges (Iverson et al., 1996; Menzies, 2012; Robinson et al., 2021). This effect has been shown to produce a self-similar grain-size distribution (Iverson et al., 1996), and it is possible the same may be true for grain shape. While the volume of subglacial meltwater influences how grains through a till column will be mobilized and therefore indirectly affects grain-shape alteration through the processes discussed above, our data suggest subglacial sediment transport is chiefly responsible for producing the largely homogenized grain shape distributions we observe. We acknowledge, of course, the Sisyphean challenges associated with untangling inherited grain shape from earlier glacial cycles or interglacial subaerial sediment transport (Evans et al., 2006), but do not think our inability to do so detracts from the findings of near grain-shape homogeneity in tills and MPD silts from a geographically-diverse sample population.
4.2 Production of meltwater silts

Subglacial processes responsible for generating glacial silts and the “terminal grain-size mode”, or the smallest size to which a grain can be comminuted based on its mineralogical structure, have been explored through field observations and controlled experiments (e.g., Dreimanis and Vagners, 1971, 1972; Iverson et al., 1996; Crompton et al., 2019). Those works have largely converged on abrasion as a widespread, dominant process in subglacial environments (Alley et al., 2019) that drives comminution by exploiting weaknesses in the mineral fabric of larger grains (Haldorsen, 1981; Crompton et al., 2019), and the microtextural signatures of abrasion on grain surfaces include different step and fracture types (e.g., Mahaney, 2002; Passchier et al., 2021). Furthermore, abrasion beneath glacial ice has been credited with rounding grain shape (Hart, 2006; Rose and Hart, 2008), which is consistent with the degrees of solidity and circularity in our results, particularly for those most mature (i.e., undergone reworking by multiple glacial advance and retreat cycles) sediments from West Antarctica (Figs. 4, 5).

We observe microtextures resulting from abrasive processes, including conchoidal fractures, arcuate and straight steps, parallel and sub-parallel fractures, on a large proportion of grains from both MPD and till samples (Fig. 6). The abundance of fracture types, edge abrasion, and other microtextures imparted through sustained stress and grinding in addition to the low occurrence of v-shaped percussions on both grain populations strongly suggests the grain-size production of the ~10 μm meltwater-silt mode results from abrasion and grinding at the base of glacial ice, rather than the comminution of grains during subglacial hydrologic transport (e.g., Schroeder et al., 2019). Witus et al. (2014) reached a similar conclusion after examining sand microtextures from MPDs and tills collected offshore PIG (material which we also include in this study, Table A1). Collectively, our results provide grain-scale evidence supporting an inferred subglacial origin for MPDs based on shared grain-size modes (Witus et al., 2014; Simkins et al., 2017; Prothro et al., 2018) and geochemical similarities (Lepp et al., 2022) with till and ice-proximal diamicton.

Although we did not include samples from each study region due to methodological challenges (e.g., insufficient number of quartz grains present on sample stub, adhering particles obscuring quartz grain surfaces), we have found meaningful results from the data subset and have conducted what we believe to be the first quartz microtextural analysis on the silt grain-size fraction. In addition to mechanical textures that offer insight into subglacial sediment transport, we also observed silt grains that retained pre-weathered surfaces and showed signs of silica dissolution. We encourage future microtextural investigations inclusive of, or focused on, the silt fraction because of the additional context those grains may hold for glacial histories, sediment transport processes, or paleoclimate reconstructions of glaciated or formerly glaciated regions.

4.3 Subglacial hydrological inferences from grain micromorphology

While we do not observe homogeneity in grain-shape distributions of MPDs as striking as is seen with grain size (e.g., Witus et al., 2014; Prothro et al., 2018; Jennings et al., 2022; Lepp et al., 2022), we do find that median circularity (Fig. 5) and eccentricity of all MPDs in this study vary by less than 10 % and that distributions overlap with one another; however,
because shape distributions also overlap with till and ice-proximal diamicton grains, we cannot describe the MPD grain-shape distributions as diagnostic. Similarly, we do not observe pervasive evidence of glaciofluvial transport in surface microtextures on MPDs (Fig. 6). These deposits are described as comprising largely silt and clay with grain-size modes at or below the sortable silt fraction (10–63 µm; Witus et al., 2014; Prothro et al., 2018; Jennings et al., 2022; Lepp et al., 2022). Fine silts in coastal settings (e.g., Manning et al., 2013) and glacial environments (e.g., Greco and Jaeger, 2020) behave cohesively and will form flocules with clays, which has important implications for plume migration and dispersal of MPDs into the marine environment. Silt flocules in the same size range as MPDs are experimentally shown to be stable in both freshwater and saline conditions at current speeds up to 25 cm s⁻¹ (Yawar and Schieber, 2017). In non-outburst style subglacial flow, aggregated meltwater silts would have less exposed surface area onto which intergranular collisions could impart microtextures (Vos et al., 2014). This aggregate shielding effect could explain both the paucity of fluvial microtextures and retention of mechanical textures observed on MPDs, and is consistent with inferred episodic, low-magnitude drainage styles offshore eastern Thwaites Glacier (Lepp et al., 2022).

Alternatively, sluggish flow conditions and/or short transport distances may suffice to reduce grain relief and round edges but be insufficient to impart abundant fluvial microtextures (Fig. 6). Microtexture studies on proglacial stream sediments find a positive correlation between transport distance and abundance of fluvial microtextures, but only after downstream transport distances between 3 km (Kržek et al., 2017) to at least 80 km (Sweet and Brannan, 2016) of downstream transport. For an evolving or transient subglacial drainage network through which flow is not constant or channelized, grains may be mobilized in suspension for only brief (i.e., sub-kilometer) distances before being deposited or entrained in basal ice via supercooling, where alteration through intergranular collisions is minimal (Alley et al., 1997; Creyts and Clark, 2010; Alley et al., 2019). In the absence of supraglacial input to the bed, such continuous flow over several or tens of kilometers may not be sustained. Rather, grains comprising MPDs experience short “bursts” of energy and entrainment (i.e., during subglacial lake drainage events) or mobilization within a sluggish, lower flow regime (i.e., through water films or distributed drainage) wherein fluvial microtextures are not expected (Mahaney, 2002; Sweet and Brannan, 2016). Low flow regimes and modest grain alteration in sediments from Thwaites Glacier is consistent with stratigraphic inferences from marine sediment cores collected from the Thwaites Eastern Ice Shelf (Lepp et al., 2022; Clark et al., 2023), while for other systems, like Pine Island Glacier and the eastern Ross Sea, some MPDs are interpreted to have rapidly accumulated through intensive, potentially catastrophic, subglacial drainage events (Lowe and Anderson, 2003; Kirshner et al., 2012; Witus et al., 2014; Prothro et al., 2018). MPD grains are significantly more regular and rounded than till and ice-proximal diamicton grains in these systems, which may be the result of intensive, but short-lived, drainage events not recorded in the other glacial settings.

The most significant intra-site grain-shape alteration we see is between subglacial tills and MPDs from Ryder Glacier. In some locations, MPDs deposited during early to mid-Holocene retreat of Ryder Glacier are three to over five meters thick (O’Regan et al., 2021) indicating a highly active, well-connected subglacial drainage network coeval with elevated air temperatures and enhanced surface melt production (Levcavalier et al., 2017; McFarlin et al., 2018). Such a drainage configuration and supply of meltwater to the ice bed would likely be capable of transporting water and sediments over long
(i.e., $10^1$-$10^2$ km) distances. We interpret grain-shape alteration for this system to result from the combination of younger, less rounded grains in the till source (Fig. 4) and the input of supraglacial melt to the bed, as would be most common in temperate glacial conditions. While some glacial systems in West Antarctica show significant differences in grain solidity and circularity between grain populations, it is to a lesser magnitude than is observed in Ryder Glacier. We therefore infer that quantifiable alteration of grains through meltwater action can be achieved through continuous sediment entrainment over long distances (i.e., many tens of kilometers) or through high-energy outburst-style flow, where a supraglacial supply of meltwater to the bed and younger, less reworked till grains can further enhance alteration. Conversely, the combination of mature till grains with poorly-developed channel networks, sluggish flow, and/or brief sediment transport distances may minimally or negligibly alter MPD grains from till sources. Results from Ryder Glacier suggest that a grain micromorphological approach may be valuable in distinguishing temperate from polar conditions in the stratigraphic record.

4.4 On subglacial basins as reservoirs and subglacial lake drainage

Both model results (e.g., Carter et al., 2011) and satellite observations (Wingham et al., 2006; Fricker et al., 2007; Bowling et al., 2019; Hoffman et al., 2020) indicate subglacial water can be stored in, and actively transmitted between, subglacial basins, demonstrating connected subglacial plumbing that mirrors basin-channel systems preserved on deglaciated continental shelves (e.g., Lowe and Anderson, 2003; Anderson and Fretwell, 2008; Kuhn et al., 2017; Simkins et al., 2017; Kirkham et al., 2019; Hogan et al., 2020). The importance of subglacial lakes as reservoirs of glacial melt and sediments have been evoked to explain discrepancies between annual production of basal melt and volume of water required to mobilize quantities of MPDs observed offshore (e.g., Witus et al., 2014; Schroeder et al., 2019; Lepp et al., 2022). For example, the distribution of ~120 km$^3$ of silts deposited offshore of Pine Island Glacier is interpreted to have been sourced in part by high-magnitude purging events of subglacial reservoirs of water and sediments (Witus et al., 2014). While our study includes samples from those deposits (Table A1) and results indicate significant alteration in MPD grain regularity from Pine Island Glacier tills (Fig. 4), neither our study nor the original found microtexture evidence expected from such high-energy sediment transport (Witus et al., 2014).

In general, the discrepancies between our grain-shape results and theories and observations of subglacial hydrologic transport prompt a consideration of the extent to which sediments are cascaded (Siegfried et al., 2016; Malczyk et al., 2020; Livingstone et al., 2022) downstream along with water during subglacial lake drainage events. Beneath the contemporary West Antarctic Ice Sheet, flux of meltwater between subglacial lake basins has been indirectly observed over tens of meters beneath Thwaites Glacier (Hoffman et al., 2020; Malczyk et al., 2020). Channelized meltwater drainage under modern Thwaites Glacier is inferred to extend to the grounding line from 50 km upstream (Schroeder et al., 2013), yet MPD morphologies from this region suggest discontinuous grain entrainment and nonturbulent flow (Fig. 4). In the Thor Iversenbanken region of the central Barents Sea, paleo-subglacial channels connecting basins are ~3-5 km in length (Esteves et al., 2022). While no Thor Iversenbanken samples were included in the microtexture analysis, the Z-scores indicate that grain shapes in till and MPDs are statistically the same (Table A2). This observation supports the importance of distance of subglacial hydrologic transport in
altering glacial silt morphology (Sweet and Brannan, 2016; Křížek et al., 2017). Drainage between East Antarctic subglacial lakes is recorded over distances an order of magnitude higher (Wingham et al., 2006), implying that MPDs offshore the East Antarctic Ice Sheet could show a higher abundance of glaciofluvial microtextures and/or shape alteration from till grains. Recent insights from modern subglacial lake sediments recovered in the Siple Coast region of the Ross Sea drainage sector suggest that silt-sized sediment can indeed be mobilized downstream between basins (Hodson et al., 2016) and cores from subglacial lakes could represent a high-resolution record of drainage activity (Siegfried et al., 2023). We infer from the grain micromorphology results presented here, however, that a linear, downstream transport of glacial silt through subglacial plumbing networks enroute to the ocean is unlikely. Rather, the continued dominance of features indicating subglacial transport through till deformation, with only minimal overprint of fluvial or meltwater features, suggests that while the final mode of transport and grain sorting may be by subglacial meltwater, it is unlikely this sediment transport process dominates over large areas or for extended periods of time (cf. Simkins et al., 2023).

5 Conclusions

Quantitative grain shape and microtexture analyses elucidate whether the shape of silt grains abundant in MPDs record alteration by subglacial meltwater action from their till origins. By calculating grain shape metrics on thousands of grains from six different glacial systems, we find that three-quarters of grains can be described by approximately one-quarter of possible grain circularities, solidities, and eccentricities, providing evidence for efficient subglacial transport and erosive processes operating at the catchment-wide scale. We find that MPD grains preserve surface textures diagnostic of sustained stress and subglacial grinding but only modest evidence of fluvial transport. This indicates that glacial processes are responsible for the unique grain-size production of MPDs and that, in general, alteration of grain micromorphology through hydrologic transport is recorded more prominently by edge rounding and enhanced grain regularity than by imparting of surface textures. We posit this may be due to an aggregate shielding effect and discontinuous transport distances and processes that are insufficient to leave a pervasive microtextural mark. While regional geology, glacial history, and catchment size likely influence variability in grain-shape distributions to a degree, these data suggest that the greatest grain-shape alteration occurs when till sources are younger and subglacial meltwater flux is in part supplied by supraglacial input. Grain micromorphology can be a valuable addition to traditional glacial and glaciomarine sediment analyses, in particular when subglacial drainage networks are suspected to have been very active (i.e., draining of supraglacial melt), in determining whether the origin of isolated silt laminae observed in sediment cores are of subglacial origin or result from melt-out from basal ice, and in distinguishing polar from temperate glacial conditions within the stratigraphic record. Further, we encourage combined empirical and experimental studies that incorporate grain micromorphology to quantifiably connect grain-shape alteration with transport distance to better constrain realistic subglacial sediment transport pathways to the ocean.
## Appendices

**Table A1:** Sample identification, coordinates, facies, water depth, associated glacial system or region, and reference for all samples used in this study. Relict glacial systems and regions that are no longer glaciated are italicized. ^ denotes meltwater plume deposits with no till counterpart. * indicates samples examined for microtexture analysis. Intervals indicate depth in the sediment core (with core top = 0) from which samples within the facies of interest were collected, and were chosen to avoid lithological boundaries. Negative elevation indicates water depth to core site, while positive elevation is used for reference materials. Diam. = diamicton.

Table A2: Results of two-type Z test and associated p-values performed on grain shape of meltwater plume deposit and till populations from each system. Z scores are absolute values. Shape metrics with statistically significantly different populations (Z > 3.0) are shown in bold. Difference in means for those statistically significant metrics is presented with 95% confidence interval calculated from 1,000 bootstrap replicates. Note the small values reflect both the range of the metric itself [0, 1] and support the rejection of the null hypothesis that MPD and till sample populations are the same. Abbreviations of the glacial systems/regions are the same as in Figure 1.

### Data and Code availability

The datasets generated for this study, including the MATLAB script and results of grain-shape measurements, are available through the PANGAEA database (doi: PENDING). Additional data supporting the findings in this work can be requested from the corresponding author.

### Author contribution

APL: conceptualization, data curation, formal analysis, investigation, methodology, project administration, software, visualization, writing – original draft. LEM: conceptualization, funding acquisition, methodology, project administration, resources, supervision, writing – review & editing. JBA: conceptualization, funding acquisition, writing – review & editing. MO, MCMW, ME: conceptualization, resources, writing – review & editing. JAS: funding acquisition, resources, writing – review & editing. LOP, EAP: resources, writing – review & editing. CDH, JSW: funding acquisition, writing – review & editing.

### Competing interests

Co-author E.A. Podolskiy is a member of the editorial board of The Cryosphere, albeit for different subject areas than are most relevant to the content in this study. The peer-review process was guided by an independent editor, and the authors have no other competing interests to declare.

### Acknowledgements

The authors acknowledge the captains, crews, and science parties who over the decades collected the dozens of cores sampled for this research. Funding for this research comes from a subcontract to the University of Virginia to LEM as part of the larger collaborative Thwaites Offshore Research grant (NSF OPP Grant 1738942 and Natural Environment Research Council grant nos. NE/S006664/1 and NE/S006672/1). We thank M. Esteves, V. Stanley, and the curatorial staff at the Oregon State University Marine and Geology Repository for their assistance with sample requests. D. Buskard and M. Prakash were instrumental in developing the MATLAB script. The Quanta 650 SEM is housed in the Nanoscale Materials Characterization...
Facility, and we thank the staff for providing the first author instrument training. Figures use the colorblind-friendly palette “Java” from the MetBrewer color package developed by B. R. Mills (https://github.com/BlakeRMills/MetBrewer). Data analysis and interpretation presented in this study was conducted at the University of Virginia in Charlottesville, Virginia. The University of Virginia was built by enslaved laborers on the unceded lands of the Monacan Nation, who have protected and cultivated these lands for thousands of years. The authors acknowledge and respect their stewardship of the land, past, present, and future.
